That gene-centered approach suggests that the genes do contain linguistic information, but this is untenable from a view informed by developmental biology. The notion of a linguistic genotype amounts to saying that the elements contained in it, like Merge, would be directly represented in the genes, in such a way that “there are elements of the genome that stand in a one-to-one relationship with elements of behavior” (Johnston 1987, p. 160). This is untenable, for “Genes store information coding for the amino acid sequences of proteins; that is all” (Bateson 2001, p. 157).

The Chomskyan view conflates the terms *innate* and *genetic* (as Neo-Darwinian biology does), assuming that an innate feature must be a genetic one. However, this conflation is ill-founded, for “being genetic is not necessary nor sufficient for being innate” (Wimsatt 1999, p. 160). Linguistic principles can be innate even though they cannot be seated in the genome, as shown by Longa and Lorenzo (2012).

Chomsky does not offer an overall picture of language evolution but solely of the evolution of Merge. We should be reminded that according to minimalism, the architecture of language consists of FL and two adjacent systems, A-P and C-I (and their interfaces with FL). Therefore, for language evolution to be accounted for, it would be necessary to explain how the internal syntactic objects became linked with the interfaces with A-P and

C-I (Berwick and Chomsky 2016, p. 66). Unfortunately, such a task is not really developed: Chomsky leaves aside the C-I system and its interface with the computational system. As regards A-P system, he assumes that it preexisted long before language, and after the appearance of Merge, internal thought became externalized through its secondary link with A-P. However, no proposals are offered at all about how such a link could happen, with the exception of the rather vague suggestion that a mutation could link the internal thought to the preexisting A-P system. Therefore, the only aspect Chomsky deals with is actually the evolution of Merge, leaving aside how this operation became integrated with the preexisting systems.

As regards the neurobiological foundations of language, works like Berwick et al. (2013) or Berwick and Chomsky (2016) clearly show that the only brain components taken into consideration when accounting for language and language evolution are cortical areas and circuits, like Broca and Wernicke's areas and several cortical (dorsal and ventral) pathways involved in language. Undoubtedly, the importance of cortical areas and circuits cannot be denied, but Chomsky completely ignores subcortical areas and the circuits between subcortical and cortical areas. In fact, the emphasis on cortical areas has recently been criticized by Tremblay and Dick (2016), who assert that the classical Broca-Wernicke model "is based on an outdated brain anatomy" (Tremblay and Dick 2016, p. 66), for it just leaves aside subcortical areas and connections that are crucial for language.

Conclusion

Chomsky has argued that language is part of the human biological endowment. If so, it had to evolve biologically. This entry has summarized the main points of the Chomskyan approach on language phylogeny. Although this scholar has further developed his approach since the advent of the Minimalist Program, his core ideas have remained unchanged since the 1960s: (1) language could not have evolved from animal

communication, (2) language is not an adaptation for communication, (3) FL evolved suddenly, not gradually, which means that (4) FL did not evolve by natural selection, which is a mere filter, rather than the factor responsible for complex design.

Definition

Schematic overviews of empirical evidence from a wide variety of sources and disciplines in order to evaluate the validity of hypothesized evolutionary psychological adaptations

Introduction

Although evolutionary psychology has been a fruitful and progressive research paradigm (e.g., Cosmides and Tooby [2013](#)), many scientists remain skeptical about the value of an evolutionary approach to unravel the origins of the human mind. For example, in the domain of language

evolution, Hauser and colleagues (2014) have argued that there is still a lack of empirical evidence in favor of the hypothesis that language is an adaptation. They argue that there is no fossil evidence related to language evolution in our ancestors, that the communicative skills of non-human animals are uninformative because these skills do not resemble human language, that our understanding of the genetics of language is poor, and that models of language evolution are based on unfounded assumptions. They conclude that this lack of relevant data and models makes it impossible – now and in the future – to unravel the origin of language.

Although these criticisms are valuable and welcome, they do not result in progressive science. Contrarily, they may prevent researchers from pursuing a research program on the origins of language (or other human cognitive traits, to which these criticisms equally apply), leaving many important research questions open. The question is how scientists build an evolutionary research program that is fruitful and progressive, but in addition takes these criticisms into account. Schmitt and Pilcher (2004) have proposed that evolutionary psychologists need to build a nomological network of evidence around their hypothesized adaptations in order to create a progressive research program.

Nomological Networks of Evidence

Ketelaar and Ellis (2000) argued that science most often does not follow the path as proposed by the famous philosopher of science Popper, i.e., the path of trying to falsify a hypothesis. In most cases, scientists proceed in a Lakatosian way: they assume that a particular theory is right (the “hard core”) and try to establish evidence in favor of this theory by confirming derived hypotheses (the “protective belt”). Only when the protective belt falls short will scientists abandon or change the hard core.

For example, the theory that language is an adaptation, evolved by natural selection, is the hard core for scientists working on language evolution. They derive hypotheses from this theory

and test those empirically, and, up until today, the results of these empirical studies are consistent with the hard core. There is no reason to abandon this hard core, because there is enough evidence in favor of it, despite the lack of some particular pieces of evidence as pointed out by Hauser and colleagues (2014).

The following question is how we decide whether there is enough evidence in favor of our hard core or not. Schmitt and Pilcher (2004) have proposed that evolutionary psychologists need to develop a nomological network of evidence around their hypothesized adaptation. A schematic example of such a network is presented in Fig. 1.

The oval in the middle of the network represents the hypothesized adaptation, for example, language. The eight boxes represent the protective belt around the hypothesized adaptation. First of all, it is important to start with a well-developed theory why language is assumed to be an adaptation. For example, Williams’ (1966) criteria for identifying an adaptation might be helpful here. Other possibilities are theories about specific selection pressures, cost-benefit analyses, game theoretical simulations, and computer modelling. Second, we may gather psychological evidence in favor of our theory, for example, by performing behavioral tests and surveys or by designing experiments to test for developmental or cognitive specificity. Third, we may gather medical evidence, for example, by collecting the results of fertility and fecundity studies or studies on physical and mental health, including psychiatric disorders. Fourth, we may gather physiological evidence, for example, by doing research on the association between brain and behavior or neurotransmitters and hormones. Fifth, we may gather genetic evidence, for example, by doing twin studies or genotype-phenotype mapping. Sixth, we may gather phylogenetic evidence, for example, by conducting animal studies, comparative research, or paleontological studies. Seventh, we may gather hunter-gatherer evidence, by using studies from cultural anthropology, ethnographic studies, and human behavioral ecology. Eighth, we may gather cross-cultural evidence, for example, by performing research on human universals and ecology-dependent variability.

Nomological Networks of Evidence, Fig. 1 Example of a nomological network of evidence (Adapted from Schmitt and Pilcher (2004) and Ploeger and van der Hoort (2015))

Following Schmitt and Pilcher (2004), nomological networks of evidence may vary along two dimensions: evidentiary breadth and evidentiary depth. In a nomological network such as the one presented in Fig. 1, the breadth may vary from one (only evidence from a single discipline) to eight (evidence from all eight different disciplines). Having filled in only one box of evidence would be considered a minimal level of evidentiary breadth, two or three boxes a moderate level, four or five boxes an extensive level, and six or more boxes an exemplary level of evidentiary breadth.

The evidentiary depth of evidence includes the total number of supportive research findings, but most of all the quality of the studies. So empirical studies with, for example, multiple modes of measurement, a control group and a minimal sampling bias count up more on the dimension of evidentiary depth than, for example, a single self-report survey with only western university students.

Examples of Adaptations for Which a Nomological Network of Evidence Has Been Build

According to Schmitt and Pilcher (2004), the following hypothesized adaptations have reached the level of at least moderate evidentiary breadth and depth:

- *Pregnancy sickness* (both exemplary breadth and depth)
- *Incest avoidance* (exemplary breadth and extensive depth)
- *Men's short-term desire for sexual variety* (extensive breadth and moderate depth)
- *Easily learned fear of snakes* (both moderate breadth and depth)

Schmitt (2014) added to this list:

- *Women's short-term desire for men with "good genes"* (both extensive breadth and depth)
- *Men's long-term desire for women that show fertility related cues, such as youth and physical attractiveness* (both extensive breadth and depth)
- *Women's long-term desire for men that show the ability and willingness to invest in herself and her offspring* (both extensive breadth and depth)

Honing and Ploeger (2012) added to this list:

- *Musicality* (both extensive breadth and depth)

Ploeger and van der Hoort (2015) added to this list:

- *Face recognition* (both extensive breadth and depth)

Conclusion

To conclude, building a nomological network of evidence around a hypothesized adaptation is a fruitful and progressive way to show the existence of a psychological adaptation. Instead of focusing on data that are not available (e.g., Hauser et al. 2014), this approach promotes an optimistic view on the broad range of possibilities to collect empirical evidence, and it motivates researchers to look beyond their traditional ways to gather data and to start interdisciplinary and cross-cultural collaborations.

Definition

Non-associative learning is the simplest yet fundamental form of learning that does not require

stimuli association or pairing. This means that animal species alter their response upon exposure to a single event or stimulus. Behavioral responses become attenuated or augmented after repeated or prolonged stimulation. Habituation and sensitization constitute the two major forms of non-associative learning and are opposite to each other in terms of the elicited responses upon continual presentation of the stimulus. In contrary, associative learning involves the presence of paired stimuli in order for change to occur. Naturally, it is suggested that non-associative learning likely came first in the hierarchy of evolutionary history, and then associative learning followed (Pereira and van der Kooy 2013).

Introduction

The mechanisms underlying non-associative learning have received great attention from the earliest of times and continue to puzzle researchers up to this day. There is a growing body of literature exploring these processes and how they influence human behavior and learning, yet there is a vast bulk of delineations to be made. Nevertheless, the current state of literature provided fundamental information that can be further utilized by future investigations. Theoretical frameworks can be applied in context of any field seeking for explanations of human complexity and pathology development.

Theoretical Background

Several influential non-associative theories have historically been proposed (Thompson 2009). These theories constitute the early work of Sokolov (1960) and Wagner's (1979) revision of Konorski's Gnostic Hypothesis and Grove's and Thompson (dual-process theory; 1970).

Sokolov (1960) was the first to propose a comprehensive theory of habituation (*Stimulus-Model Comparator Theory*). In short, Sokolov's theory stated that when a stimulus appears repetitively, the brain cortex forms a model (or a memory) of the stimulus. Each incoming stimuli was

compared to the model, and if the incoming stimulus matched the model, responding was inhibited otherwise an orienting response was evoked. The exertion of inhibition was thought to yield habituation; thus habituation was perceived as purely inhibitory. Even though Sokolov's work intrigued a great bulk of follow-up investigations in habituation in the humankind, the theory was not applicable to animals who do not possess a cortex, contrary to the dual-process theory.

Another comparator theory constitutes the work of Konorski on habituation which shared many similarities with Sokolov's theory. Wagner (1979) revisited Konorski's ideas, but he concentrated on the roles of short-term memory and associative mechanisms. A stimulus is carried by afferent/sensory neurons toward a memory system, the Gnostic assembly, and to the arousal system. With repeated stimulation, a gnostic unit is formed, which is a near-accurate neuronal model or memory of the stimulus. As this model develops, it increasingly activates an inhibitory system that inhibits the arousal system, consequently causing habituation. Wagner added a process mediator, an associative network where contextual cues have to pass through in order to excite stimulus models in memory and a process of transient memory (short-term memory). In short, what these scientists advocated is that long-term habituation requires the storage of a stimulus in long-term memory and that it is associated with external cues for retrieval from long-term memory.

Finally, the most prominent non-associative learning theory was composed by Grove and Thompson (1970). Neurophysiological concepts were combined with concerns of human ethology and evolution to create the *dual-process* theory. This theory advocated that repeated stimulation would produce two independent processes that could both be active at the same time: decreased responsiveness (habituation) or increased responsiveness (sensitization). The authors believed that the two processes take place in different parts of the nervous system. Scientists believed that habituation took place in the so-called S-R system (reflex arc) that controls reflexes, whereas sensitization occurred in the "state system" which is

responsible for the level of readiness to respond. The state system requires arousal to become activated, while the S-R system is activated with the presentation of an eliciting stimulus. Further, habituation is thought to be stimulus-specific and involves learning, in contrast to sensitization which is not highly specific and does not require learning. However both are of relative permanence; they are expected to decay at the absence of stimulation. Contrary to Sokolov's model, the *dual-process* theory does not propose an inhibitory system.

Nevertheless, all these studies of cellular processes which facilitate learning and memory, which were mostly held in invertebrates, most certainly add to the understanding of the underlying physiological processes of learning in the majority of living animal organisms, but mechanisms such as habituation and sensitization are far more complex and necessitate further exploration.

Habituation

Habituation constitutes an essential process of behavioral adaptation, as it assists in filtering out the large amounts of information received from the surrounding environment that are likely irrelevant or less important, thus shifting attention to more important to survival or urgent information. The latter gives an evolutionary advantage as a result. Habituation can be defined as a decline in behavioral responsiveness to the continual presentation of a stimulus. While there is a strong response initially, the strength of the response reduces and eventually disappears with repeated stimulation. The reduction in responsiveness is neither the result of motor (muscle) fatigue nor sensory adaptation; however it is likely to be disrupted when another strong stimulus appears (dishabituation). Other factors influencing habituation include stimulus repetition, interstimulus interval, and stimulus intensity. These factors are determinant of whether short-term or long-term habituation will occur. Short-term habituation is characterized by rapid stimulations with short intervals in between; habituation is observed early; however it is short-lived as soon as stimulation ceases. On the other hand, long-term habituation is characterized by fewer stimulations over

longer periods; habituation is slower but its effects are long-lived as recovery is delayed.

In addition, in earlier writings habituation was thought to only have short-term effects (Hinde 1970); however existing literature has demonstrated that its effects can last long. Apart from its simplicity, habituation is thought to be ubiquitous; it is both a highly automated yet learned phenomenon occurring in the central nervous system (CNS) of all animal species, ranging from single-celled protozoans to humans (Thompson 2009), with studies demonstrating its occurrence in plants as well (Gagliano et al. (2014).

Thompson and Spencer (1966) presented a list of nine parameters of habituation, shared by all species. A tenth parameter was added to the list of behavioral characteristics of habituation by Rankin and colleagues (2009) and is presented as follows:

1. Given that a particular stimulus produces a response, repetitive applications of that stimulus will result in a reduced response (habituation). Most of the times, the decrease is a negative exponential function of the number of stimulus presentations.
2. If the stimulus is withheld, the response tends to recover over time ("spontaneous recovery").
3. After a multiple series of stimulus repetitions and spontaneous recoveries, habituation becomes more rapid ("potentiation of habituation").
4. The more rapid the frequency of stimulation, the more rapid and/or more pronounced is habituation.
5. The weaker the stimulus, the more rapid and/or more pronounced is habituation. Stronger stimulation might yield no significant habituation.
6. The effects of habituation training may proceed beyond the zero or asymptotic (minimum level of response) response level.
7. Habituation of response to a stimulus displays stimulus generalization to other stimuli.
8. Presentation of another strong stimulus results in disruption or recovery of the habituated response ("dishabituation").

9. After repeated application of the dishabituation stimulus, the amount of dishabituation produced habituates ("habituation of dishabituation").
10. Some stimulus repetition protocols may result in properties of the response decrement that last hours, days, or weeks. This persistence of aspects of habituation is termed long-term habituation.

Importantly the aforementioned characteristics of habituation were observed and collected through numerous studies on a variety of species; therefore they do not imply particular theories or inferences. They could be considered however as a detailed definition of habituation.

Several scientists who have studied the process of habituation provide valuable information regarding the underlying mechanisms of habituation and associated processes, demonstrating at the same time its complexity (Thompson 2009). It has been noted that the occurrence of habituation is determined and/or influenced by variations in interstimulus interval and by the organisms' ability to generalize and discriminate between the presented stimuli. Additionally, spontaneous recovery is another process thought to influence habituation's maintenance. All these concepts are further analyzed in the sections that follow.

Interstimulus Interval

The concept of interstimulus interval is frequently encountered within processes of non-associative learning, specifically habituation and sensitization (Petrinovich 1984).

Interstimulus interval can be defined as the time interval between the end of one stimulus presentation and the onset of another stimulus presentation. Interstimulus interval experiments were extensive under the work of Davis (1970) on habituation of the acoustic startle response in the rat. Generally, through Davis's series of experimental studies, it was demonstrated that the length of interstimulus interval, as well as variability (regularity), determines habituation in animals. The author compared the responsiveness of two groups of rats to a 50-msec, 120-db tone of 4000 Hz during pretest, training, and posttest

periods. During both the pretest and the posttest periods, both groups of subjects received 300 tone exposures at intervals of 2, 4, 8, and 16 s, the intervals being scheduled in an irregular order. During the training period, both groups received 1000 tone exposures; however the interval between stimuli was 16 s in one group and 2 s in the other group. Among other findings, greater reduction in responsiveness was observed in the group who received stimulation every 2 s.

In the second experiment, startle responsiveness was lower following training with regular as opposed to variable interstimulus intervals. Simply put when interstimulus interval is longer and constant, habituation is greater. Also (Davis 1970) reported quite an interesting finding; when rats were tested at 1 min or 24 h later with a variety of interstimulus intervals, habituation was greater for the group that was trained on the 16-s interstimulus interval schedule suggesting thus that short-term and long-term habituation processes may be distinguishable on the basis of the presentation and the intervals between stimuli. Specifically, it was demonstrated that short interstimulus intervals were involved in the progression of short-term habituation, while long interstimulus intervals were involved in the promotion of long-term habituation. Also, apart from the fact that high-frequency stimulation leads to more rapid response decrement, it results in faster spontaneous recovery as well Leaton (1976).

Similarly, Groves and Thompson (1970) noted that increased frequency should lead to increased habituation in the "S-R" pathway, but in the "state" pathway, it would lead to increased sensitization. All the aforementioned experiments considered together are indicative of the importance of interstimulus interval making it obvious that it can have a major effect on learning; it may delay or improve learning. Lastly, the organism's ability to determine the interval and duration of sensory stimulation is central to sensory processing; therefore impairments in that domain are likely to interfere with the process of learning.

Variations in the time between the presentations of one stimulus to the next have a determinant effect on the forms of non-associative learning; habituation and sensitization and the

occurrence of long-term and short-term habituation are dependent upon the length of interstimulus intervals (Leaton 1976). Further manipulation of interstimulus intervals will provide valuable information regarding disruptions in learning processes or even suggestions as to how to enhance learning.

Stimulus Generalization and Discrimination

Similarly, the concepts of stimulus generalization and stimulus discrimination are encountered within the context of associative and non-associative learning.

Stimulus generalization refers to a set of stimuli sharing similar properties with the original stimulus that provoked a response. *Stimulus discrimination* is the ability of an organism to respond only to the original stimulus and not to other similar stimuli. Both concepts are inherent mechanisms in the processes of associative and non-associative learning, and for both processes to take place, it is essential that a stimulus model should be stored in memory in order for comparisons with new stimuli to take place.

To begin with, generalization occurs when an organism produces the same response to different stimuli. Stimuli who exhibit analogous properties to the original are more likely to provoke a response: habituation. There could be variations in terms of the level of pitch, brightness, loudness, and so on; however if these variations deviate significantly from the properties of the original stimulus, generalization will not occur; hence it is more likely that habituation will not occur either (Teyler et al. 1984). Stimulus generalization of habituation can only be determined when a second habituation series is done with the use of a novel stimulus. With a comparison of the rates of habituation between the original and the novel stimulus, the amount of generalization will be demonstrated. More rapid habituation in the second series would be indicative of generalization, whereas similar rates between the two series would be indicative of a lack of generalization (Petrinovich and Widaman 1984).

On the other hand, if stimuli are rather dissimilar than similar, the opposite process of stimulus generalization, the so-called stimulus

discrimination will be activated. In *stimulus discrimination* the organism shows the ability to differentiate between similar stimuli and only to respond to a specific stimulus; hence the organism responds differently to the two stimuli. *Stimulus discrimination* is particularly important in the process of habituation, as it can be used to dismiss sensory adaptation and fatigue as an alternative explanation of the occurrence of habituation. Further, *dishabituation* is indicative of the ability to discriminate, therefore ending habituation (Thompson and Spencer 1966). It is important to clarify however that dishabituation occurs due to repetitive stimulation of a completely irrelevant stimulus and should not be thought of as the same as stimulus discrimination.

Finally, stimulus generalization is useful because it allows for learning to take place quickly in new situations that share similarities with past experiences and promotes the transfer of skills into similar situations thus saving time and effort. Stimulus discrimination offers assistance in a practical level as well.

Stimulus generalization and discrimination are crucial processes in learning, and both are of paramount importance to adaptation. Clearly any organism that lacks such abilities would have minimal chances of survival. There are well-known experiments undergone within the concept of conditioning (Pavlov's and Watson's experiments) that illustrate the stimulus generalization and the stimulus discrimination concepts more elaborately.

Spontaneous Recovery

Spontaneous recovery refers to the recovery of a habituated response. When a sequence of stimulus presentations is interrupted, the object at hand will return to its earlier stage and the behavior will recover over time. In a series of experiments undergone by Rankin and Broster (1992) on the nematode *Caenorhabditis elegans*, mechanical stimuli were delivered at four interstimulus intervals (2, 10, 30, and 60 s) in order to investigate the effect of interstimulus intervals in the development and maintenance of habituation. Results indicated that recovery from habituation was dependent on some factors. One of these factors

is the length of interstimulus intervals; it was observed that recovery from habituation was faster when short interstimulus intervals were applied rather than longer interstimulus intervals. That is, long-term habituation prevents recovery. Also, the rate of recovery varied according to which response level each subject exhibited on the habituation curve. The recovery of animals on the lowest response level appeared to be determined by interstimulus interval and not by the further addition of stimuli. Interstimulus interval recovery rates did not differ even though the number of stimuli the worms received was significantly bigger (60 Vs 10) in the second group. In short what was evident is that the frequency of stimulation during habituation training was the one to determine the rate of spontaneous recovery.

Moreover, Rankin and colleagues (2009), upon revisiting the characteristics of habituation originally described by Thompson and Spencer (1966), revised a point concerning spontaneous recovery. It is described in the characteristics that when a sequence of stimulus presentations is interrupted, the object at hand will return to its earlier stage and the behavior will recover over time. Rankin and colleagues (2009) revised this characteristic by adding that sometimes the response recovers completely, but sometimes it recovers only partially depending on the time frame that recovery was examined.

Further, when stimulus presentations and spontaneous recoveries are given repeatedly, the phenomenon of *potentiation of habituation* is observed. Here, the decrement in response that follows spontaneous recovery (i.e., habituation) becomes gradually more rapid with each application of spontaneous recovery. Moreover, the process of spontaneous recovery can be disrupted with the presentation of a new, strong stimulus (sensitization).

Lastly, it is crucial to note the importance of spontaneous recovery; it is the second way, with stimulus discrimination being the first way, to distinguish sensory adaptation and fatigue from habituation. With regard to learning, this process demonstrates that even though a response might disappear, it does not necessarily mean that it has

been withdrawn from memory and that it will never reoccur.

Experiments on the lowest living forms illustrate the phenomenon of spontaneous recovery, and those indicate that spontaneous recovery is highly determined by the frequency of stimulus presentation. These experiments provided a special insight on the underlying processes of habituation.

Having analyzed the underlying processes of habituation (interstimulus interval, stimulus generalization and discrimination, and spontaneous recovery), it has been demonstrated that they are interconnected and influence the occurrence and maintenance of habituation. Habituation is one of the simplest forms of non-associative learning; it is found in all animal species, and it is a highly complex yet essential process of the evolution of learning. On the section that follows, the opposite process of habituation, called sensitization, will be explored along with its underlying processes and types.

Sensitization

Sensitization is a non-associative learning process that leads to increased responsiveness to a stimulus and is considered complementary to habituation. The increase in responsiveness or behavior is due to the exposure of a strong, most commonly noxious stimulus that is causing pain. It is therefore logical to infer that sensitization's adaptive value is high, as it protects an organism from predators and other potential dangers (Eisenstein et al. 2001). During sensitization an organism will only respond to high- or strong-intensity stimulus rather to low-intensity stimulus as it happens in the case of habituation. This constitutes a fundamental difference between the two processes, but it is not limited to that; sensitization can occur without necessarily having continual stimulation (a single, strong stimulus can sensitize the organism). Further, sensitization has a limited time course and relatively short-term effects; however that depends on the intensity of the stimulus (Eisenstein et al. 2001).

Petrinovich (1984), based on the "dual-process" theory, outlines eight basic assumptions in relation to sensitization and are listed as follows:

1. Sensitization occurs in the “state” system and not in the “S-R” system.
2. During habituation training, sensitization appears initially but then deteriorates.
3. The amount and duration of sensitization are directly related to stimulus intensity. At high intensities, sensitization is directly related to stimulus intensity and frequency. However, at low intensities there may be little or no sensitization.
4. Sensitization decays spontaneously as soon as the sensitizing stimulus has stopped.
5. Repeated presentations of a sensitization stimulus result in gradual reduction of sensitization.
6. Response sensitization displays generalization.
7. Dishabituation is considered as an instance of sensitization.
8. Temporal conditioning of sensitization may occur.

Sensitization has not received as much attention as habituation did; however especially enlightening was the study of the neural basis of sensitization, in laboratory settings, with the mollusk *Aplysia* and the work of Kandel, as well as with the work of others on *kindling* and *long-term potentiation*.

Long-Term Potentiation

Sensitization and long-term potentiation are similar processes but differ in their site of application. Sensitization occurs in specific pathways (state), while long-term potentiation occurs in synapses. However, the process of sensitization involves the mechanism of long-term potentiation.

Long-term potentiation of synaptic transmission is a major mechanism for investigating learning and memory in the synaptic level. Long-term potentiation is found in several regions of the brain, with the most prominent being the hippocampus thus its obvious involvement in the neural basis of some forms of memory (Cooke and Bliss 2006). It is a form of synaptic plasticity and is defined as a persistent increase in synaptic strength following high-frequency stimulation of a chemical synapse. High-frequency stimulation causes an increase in the efficiency of synaptic

transmission, therefore enhancing the efficiency of the signal. For the induction of long-term potentiation, the activation of excitatory receptors is required (Cooke and Bliss 2006). Bliss and Collingridge (1993) reported on the properties of long-term potentiation that differentiates it from other forms of synaptic plasticity: *input specificity* (it does not spread to other synapses), *associativity* (when a weak input of a single pathway is insufficient for the induction of long-term potentiation, simultaneous strong stimulation of another pathway can potentiate the weak stimulation), and *cooperativity* (apart from strong stimulation, long-term potentiation can be induced by the cooperation of many yet weaker stimulations). Since long-term potentiation occurs when a neuron shows an increased excitability over time due to a repeated behavior, and the heightened synaptic transmission leads to the amplification of responses (i.e., pain), its involvement with the process of sensitization is high.

While the long-term potentiation of synapses in localized cell tissues seems to provide an elegant substrate for learning and memory, researchers turn their attention into experiments with the whole living organism (in vivo experiments). Morris et al. (1986) provided for the first time some data from in vivo experiments in which it was indicated that long-term potentiation was essential for the construction of memories. Using rats, Morris and colleagues were able to examine their spatial memory by inserting an N-methyl-D-aspartate (NMDA) blocker drug in their hippocampus, a brain structure implicated in learning. NMDA is a glutamate receptor and an ion channel protein within nerve cells, and it is responsible for the control of synaptic plasticity and memory function. Initially rats were trained to swim in a water maze, in order to find the platform hidden beneath (in the center and the sides of the pool) and escape. As soon as the rats were able to locate the platform, they were separated in two groups. One group constituted the control group, while rats of the second group received the drug that blocks NMDA. Then both groups of rats were exposed to the water maze spatial memory task with the rats of the control group being successful in locating the platform and escaping the pool.

Contrary, the second group of rats exhibited impaired performance, as long-term potentiation could not be induced indicating thus damage in the hippocampus. This series of experiments indicated that long-term potentiation is implicated in learning and memory processes.

Finally, dysfunctions in the process of long-term potentiation are thought to be implicated in mood disorders (Post 2007) and neurodegenerative diseases as Parkinson's (Cooke and Bliss 2006). Long-term potentiation is a fundamental process in a cellular level with implications in the process of learning.

Kindling

Both sensitization and kindling are forms of learning occurring in some parts of the nervous system, and the common characteristic they exhibit is the increase in responsiveness. Kindling can be thought of as a specific type of sensitization.

Kindling became known to the scientific world in the late 1960s through the published work of Goddard (1967) on the neurobiology of learning and later after the application of Goddard's model on the study of epilepsy. Goddard (1967) ran a series of experiments on rats where, in order to investigate their abilities to learn tasks, he administered electrical stimulations in various regions of their brains. With daily repetition of the electrical stimuli, the rats began seizing. That response, however, was astonishing, as the administered stimuli were too low to induce seizures. Even more surprising was the final observation of the rats having unprovoked seizures, that is, seizing without stimulation. In sensitization repetitive stimulation produces a full response. A full response can be elicited even with lower stimulus levels than the original stimulus. It appears that a decrease in the threshold of excitability develops leading to the automatic occurrence of the response, without external stimulation. Eventually, with further repetition, the response occurs spontaneously, in the absence of any stimulus, demonstrating thus the phenomenon of kindling. The changes caused by kindling seem to be long-term, but they are not permanent.

Kindling is universal across species (from frogs to humans) and throughout the brain, and it

was the first neuroplasticity phenomenon suggested to give information on memory processes. At a first glance, it may seem awkward to imply that epileptic seizure activity could be interconnected learning; yet, it is plausible that the diverse mechanisms constituting kindling and learning interconnect and share several common mechanisms. In effect, under this conceptualization, both kindling and learning can potentially be considered as phenomena of neuroplasticity. However when kindling was compared to long-term potentiation as to which neuroplasticity phenomenon was more appropriate for modelling memory processes, long-term potentiation appeared to dominate, mostly because long-term potentiation was observed under normal neural activity contrary to kindling that was observed under seizures.

Further, kindling constitutes the model for the development or recurrence of medical (epilepsy) and psychiatric illnesses such as addictions and mood disorders (Post 2007). Goddard's model has been referred to as the "kindling model for epileptogenesis" as it is the most frequently used model for temporal lobe epilepsy with complex partial seizures. It is used by scientists to study the effects of repeated seizures on the brain. What was demonstrated in the experiments with rats, the same applies for humans; a seizure may raise the possibility that more seizures will occur since repeated stimulation "lowers the threshold" and paves the way for seizures to reoccur (Dennison et al. 1995; Racine 1978). In an attempt to better understand the occurrence of epileptic seizures, many scientists including Racine (1978) have turned their attention to the underlying mechanisms of kindling, in neurotransmitter systems and intracellular mechanisms, as well as genes.

Goddard's experiments suggest that the processes underlying kindling and learning interconnect and possibly have similar underlying mechanisms. Kindling is of particular importance in disorders where recurrence is involved: in addictions (relapse) and mood disorders (recurrent episodes), but its underlying mechanisms are yet to be refined by empirical investigations.

Drug Sensitization

Drug sensitization is a process frequently encountered in the literature of the field of addictions and pharmacology, and it is an essential process toward the understanding of drug action and use.

Drug sensitization is a type of sensitization, and it refers to an increase in drug effect upon continual exposure to a drug in the organism, which was previously exposed to the drug. With repeated drug administration, gradual and incremental neuroadaptations are produced, that make animals hypersensitive to the specific drugs. Even though users or abusers will be keeping the same dosage levels, drug effects will be greater and greater; therefore they would become intoxicated even in small doses. Using repeatedly a drug but with some pauses in between causes greater sensitization compared to taking a single dosage or even taking repetitively the drug. Moreover, sensitization is promoted if periods of use are alternated with periods of abstinence. When a person who is sensitized let's say to cocaine and abstains from use for some time, he/she is at risk of fatal overdosing at reuse (Steketee and Kalivas 2011; Robinson and Berridge 2008). Known addictive substances, where sensitization has been observed in, are cocaine, amphetamines, morphine, nicotine, and even alcohol; importantly not all drugs are subject to sensitization, mostly stimulants. In addition, the selected route of drug administration as sensitization is influenced by the speed or the time it takes for a drug to reach the brain. Sensitization in the case of drugs is long lasting with its effects on behavior and cognition lasting for years even with abstinence; however factors such as the time lapse between dosages, the choice of drug, the age and sex of the user, and genetics influence the strength of sensitization. Due to these factors, vulnerability to sensitization differs between individuals (Steketee and Kalivas 2011). That provides an insight into the long-asked question of why some users become addicts while others do not get addicted.

The sensitization of behavior and other psychological or psychomotor functions implies neural sensitization. Drugs seem to alter or reorganize neural systems and neurotransmitters, and even though causal relationships are yet to be

established, neuroadaptations seem permanent. The permanency of changes in neurotransmitter circuits have crucial implications on the matter of cravings and relapse. Of special importance is the sensitization of the mesolimbic pathway of the mesotelencephalic dopamine system. Since dopamine is responsible for the motivation to go after pleasure and happiness and fulfill our “wants,” drugs come to jeopardize this process by making dopamine hyper-reactive, consequently increasing the prominence of drug cues, hence the intense cravings (Robinson and Berridge 2008). In the matter of cravings and relapse, kindling is thought to be implicated. The aforementioned comprise the “incentive sensitization” theory of addiction developed by Berridge and Robinson (1998) and is noteworthy of further reading.

Drug sensitization is a complex process influencing drug users in a cellular level and in consequence in a behavioral level.

Having analyzed some types of sensitization and the underlying mechanisms, it has become evident that sensitization is of significant value as it has helped organisms to adapt in potentially dangerous situations and evolve. While sensitization's underlying mechanisms are still under investigation, research thus far has been able to provide data for the better understanding of learning phenomena and the appearance and treatment of pathologies. A significant contribution to the study of sensitization constitutes the work of Kandel with the mollusk *Aplysia*, described in detail in the sections that follow.

Eric Kandel

Eric Kandel is a well-known neuroscientist for his research on memory and learning for which he shared the Nobel Prize in Physiology or Medicine in 2000. His breakthrough came through his pioneering work with *Aplysia*, which provided a wealth of information regarding non-associative learning and its forms.

Kandel was born in Vienna on 7 November, 1929. His mother, named Charlotte Zimels, was born in 1897 in Kolomea, which was at that time part of the Austro-Hungarian Empire. Kolomea is now a part of Ukraine and has been renamed Kolomyia. She came from a well-educated

Jewish middle-class family. His father, Hermann Kandel, was born in 1898 in Olesko, a small town then part of the Austro-Hungarian Empire, now part of Ukraine, and was brought up in a poor family. At the beginning of World War I, his parents moved to Vienna, Austria, where they met and married in 1923. By the time they had their first child, Lewis, his father, was the owner of a toy store. Eric Kandel was born 5 years later. They lived in a middle-class neighborhood, in a small apartment, and as both of his parents were occupied with the toy business, a housekeeper was looking after the children. Approximately when Eric Kandel was 10 years of age, he moved to Brooklyn, in the United States, with his family. His parents had to work hard to bring it along, and adjusting was difficult. However Kandel speaks highly of his parents for their determination and hard work to raise him and his brother; they were not only successful in their jobs but managed to support both of their children on their chosen paths.

After their relocation, Kandel had already involved in an elementary school, of which he graduated in 1944. After he graduated from the Yeshivah of Flatbush Elementary School, he went to Erasmus Hall High School, a local public high school in Brooklyn. By then, Kandel was already fluent in several languages, including Hebrew and Greek, and was involved in several activities including, among others, soccer, music, and writing. He then applied to Harvard College and managed to be admitted and earn a scholarship as well. He majored in European history and literature. After some interactions he had with some psychoanalysts, he became more interested in understanding the human mind, and that was determinant in furthering his studies by becoming a medical doctor. During his studies he became increasingly interested in the biological basis of the mind. By 1956, he graduated from the New York University School of Medicine. He then joined a research team in Harry Grundfest's laboratory at Columbia University where they were dealing with research on a cellular basis. Grundfest was then a pioneer on the use of oscilloscope to measure action potential conduction velocity on the axons of neurons. After the

intracellular recordings of electrical activity of the cerebral cortex of vertebrates done with Grundfest's team, Kandel's interest was directed to the study of the electrophysiology of neurons of invertebrates, influenced by the work of Kuffler. The shift occurred from Kandel's belief that the mechanisms of memory storage were possibly well-preserved in phylogeny and that the cellular analysis of learning in low-level animals would reveal universal mechanisms that were also found in more complex organisms. His belief was validated shortly after The Official Website of the Nobel Prize (2018).

Around 1957, when Kandel joined the Laboratory of Neurophysiology at the US National Institutes of Health, he focused on the study of the hippocampus. William Beecher Scoville and Brenda Milner were working at that time on the hippocampus and noticed that after hippocampus excision, a patient no longer had the ability to form new memories. Kandel was greatly intrigued yet puzzled by the findings of these researchers and begun examining the electrophysiology of hippocampal pyramidal neurons. At that time he was working with Alden Spencer, another great neuroscientist who was also interested in the biology of learning and memory. They managed to provide electrophysiological evidence for the formation of action potential in the dendrites of hippocampal neurons, not only in the axons as it was previously suggested. These dendritic action potentials were the trigger for firing at the axon hillock. They also recorded spontaneous pacemaker-like activity in these neurons; they noticed that firing took the form of bursts of spikes. Lastly their research outcomes indicated the presence of strong recurrent inhibitory processes in the hippocampus resulting in prolonged inhibition. Kandel began to realize that memory storage must rely on modifications in the synaptic connections between neurons and that the complexity of the connections found in the hippocampus made it an inappropriate system for the study of synapses. That's when he selected the simplest animal model for his study, *Aplysia* (sea slug). He conducted electrophysiological analyses of the synaptic changes involved in learning and

memory storage and provided breakthrough information that seemed to correspond to the simplest forms of learning (habituation, sensitization). It is noteworthy to mention that during the years 1963–1965, Kandel begun his academic career as an instructor in the Department of Psychiatry. In 1965, he accepted the position of Associate Professor at New York University, and it was during that time period that he started working with *Aplysia*. By 1974 he became a Professor, in the department of Physiology and Psychiatry, in Columbia University and later the Director of the Center for Neurobiology and Behavior. Around 1984 he became a Senior Investigator at Howard Hughes Medical Institute at Columbia University (The Official Website of the Nobel Prize 2018).

On a personal level, Kandel has already met and married (1956) the French, Denise Bystryin. They had two children, Paul and Minouche, and are currently proud parents and grandparents as well, as all family members have thrived. His wife is a professor in the Department of Psychiatry and in the School of Public Health at Columbia University and has worked extensively on the field of addictions and drug abuse in adolescents. For nearly 40 years, they have been living in the Bronx, and together they enjoy a variety of hobbies and interests: visual arts, classical music, and opera, and they passionately collect art and antiques (The Official Website of the Nobel Prize 2018).

Kandel's experimental research work has been extensive and greatly influential for the scientific world. He counts numerous publications that have not only been enlightening but also determinant for the course of future research. For his excellence and achievements, he has received more than 20 awards among them the Lester N. Hofheimer Prize for Research of the American Psychiatric Association (1977), the American Association of Medical Colleges Award for Distinguished Research in the Biomedical Sciences (1985), the Gairdner International Award of Canada for Outstanding Achievement in Medical Science (1987), the Harvey Prize in Israel (1993), the Wolf Prize in Biology and Medicine (1999), and the Nobel Prize in Physiology or Medicine

(2000) which he shared with two other colleagues. He has also received honorary degrees from nine universities, three of which are European (The Official Website of the Nobel Prize 2018). His awards indicate worldwide recognition of his work.

Eric Kandel's life story and academic path, apart from being motivational, have left the academic society with solid grounds to work on and has provided breakthrough information adding up to the understanding of how the human mind works. His work focused on the physiological basis of learning under which he explored short- and long-term memory, neural circuits, and synaptic processes through experiments with *Aplysia*.

Aplysia

Aplysia became known to the scientific world through the pioneer work of Kandel which provided a wealth of information regarding non-associative learning and its forms (habituation and sensitization).

Aplysia is a species of sea snail, commonly referred to as sea hares because of their posterior tentacles that protrude like ears do in hares. Among low-level organisms, *Aplysia* has become a fitting model for studies of how neurons and neural circuits regulate behaviors. What attracts scientists into studying them is their simplicity and the huge size of their neurons, which are easy to manipulate and work with. Also, *Aplysia* exhibits abilities on learning establishing thus its appropriateness for applying cell biological approaches to the investigation of learning and memory mechanisms (Moroz 2011).

Of particular interest to Kandel and colleagues was the gill and siphon withdrawal defensive reflex of *Aplysia*. *Aplysia* has a mantle cavity on its dorsal surface that protects the gill. The gill lies beneath the mantle shelf, which terminates at the back of the cavity in a fleshy, funnel-shaped spout, the siphon, which contracts to eject water from the gill. A two-component reflex is triggered when stimulation is applied to the siphon (mantle shelf) causing both the siphon and the gill to be retracted, protecting the organism from potential threat. These two components consist of two involuntary reflexes, the so-called siphon

withdrawal reflex (SWR) and the gill withdrawal reflex (GWR). The gill and siphon withdrawal reflex (GSWR) is mediated by distinct neuronal pathways, enabling scientists to record activities on the synaptic and neuronal level and to directly link synaptic plasticity to behavioral plasticity. The neural circuits of these reflexes are comprised of monosynaptic connections from sensory neurons to motor neurons, as well as polysynaptic connections containing excitatory and inhibitory interneurons. Kandel's and associates' work on this invertebrate animal regarding the cellular mechanisms underlying habituation and sensitization observed that while light siphon stimulation would naturally cause retraction, repetitive siphon stimulation produced short-term habituation lasting for a few hours. On the other hand, long-term habituation was demonstrated by repeating multiple training sessions across several days. A single habituation training session consisting of regular trials separated with a time interval of 30 s produced typical reductions in response of the siphon withdrawal reflex. The replication of these training sessions once per day for 4 days produced a progressive buildup of habituation within each session. Habituation preservation was tested the next day and weeks 1 and 3 after training, and when compared to group, the experimental group exhibited greater habituation. The gill withdrawal component of the reflex was also tested for long-term habituation with the same procedures showing that siphon training produces long-term habituation in both components of the reflex (Castellucci et al. 1970). Furthermore, in another series of experiments, noxious shocks at the rear produced an increase in the siphon withdrawal reflex and in the gill withdrawal reflex. A single shock increased the reflex for 15 min to an hour. After repeated shocks sensitization seemed to last up to several weeks. Four brief noxious electrical shocks were applied daily for 4 consecutive days. Sensitization retaining was measured again at day 1 and weeks 1 and 3. Also greater sensitization was observed with the addition of more shocks and by spacing the training sessions (two daily shocks within 10 days) (Pinsker et al. 1973).

Generally it was indicated that short-term and long-term habituation results from homosynaptic depression of excitatory neurotransmission, while heterosynaptic facilitation of the sensorimotor connection caused sensitization. Habituation was not brought up by changes in the activity of sensory or motor neurons. Specifically sensory neurons release less neurotransmitter because of changes in calcium channels regulating neurotransmitter release, leading to the functional inactivation of the synapse in the long term. Nevertheless habituation still occurs after direct electrical stimulation of the motor nerve, avoiding that way the sensory receptors. This is essential as it reveals that the reduction in response is not due to sensory adaptation. Furthermore, motor fatigue is also eliminated by showing that direct stimulation of the motor neurons can still provoke a normal reaction after habituation has occurred. Carew (1984) provides for more detailed description of the work with *Aplysia*.

Conclusion

Research on non-associative learning and its forms indicates that it precedes associative learning in the evolutionary sequence. Associative forms of learning arise from the neural mechanisms used in non-associative learning, making non-associative learning an inevitable component of associative learning.

Habituation and sensitization with their neural substrates are complex forms of plasticity which have been implied as a causal or maintaining mechanism in a wide range of pathologies. Understanding their impact on behavior necessitates constant consideration and evaluation of multiple output measures through the application of the different theories of non-associative learning. Even though mechanisms were studied in the simplest type of existence, they were proven to be remarkably rich and complex. In depth investigations of these processes provide new understandings for the better management and possible prevention of pathologies through the development of effective therapeutic interventions, both pharmacological and psychological.

Definition

Intelligence in animals can be defined in terms of problem-solving ability, both acquisition to solve problems and the ability to generalize what is learned to novel situations. Intelligence may also be measured in terms of behavioral flexibility, which is comprised of inhibition and innovation components and which concerns adaptability to new and changing environments.

Introduction

Two main categories of inquiry derive from the central topic of nonhuman intelligence. The first category entails questions regarding species differences. Are some species of animals considered more intelligent than others? If so, which species are considered most intelligent? These questions should lead one to ponder whether it is fair to compare different species on the same tasks. The second category entails individual differences. Do individuals within a species vary in their intelligence, and how can these abilities be assessed? It is unknown to what extent nonhumans show the same variability in intelligence that humans do. Variability within a species likely depends upon the environment that it inhabits (Sol 2009). One might not expect intellectual functioning to vary within members of short-lived species whose environments are relatively constant and whose behavior is largely innate or canalized. On the other hand, one would expect variability in intellectual functioning in species that live in constantly changing environments, who face foraging challenges (Byrne 1997), and who live in complex social groups (Jolly 1966; Humphrey 1976). Humans of course live in arguably the most complex social groups and have been the most inventive in terms of extracting sustenance from the environment. They exhibit significant variability in intelligence, ranging from intellectually challenged to extremely gifted. But before delving into possible answers to these broad questions with nonhumans, it is important to define intelligence with regard to nonhumans and to consider how it might be assessed.

Intelligence is difficult to define, even in humans. Most popular tests of the nebulous construct, such as the Stanford-Binet (Roid 2003) and Wechsler Intelligence Scales (Groth-Marnat et al. 2000), focus on assessing processing speed, working memory, analogical reasoning, verbal reasoning, quantitative skills, and other basic reasoning abilities. These tests are based on the notion of a general factor, “*g*” that is innate, stable, and reflects an individual’s capacity to acquire and to apply knowledge (Spearman

1961). Spearman’s view also revolved around the notion that, whereas there may be different types of intelligence, they are all correlated. Other more liberal views of intelligence have been proposed such as Sternberg’s triarchic theory of intelligence that focuses on practical, creative, and analytic components that comprise what he described as “successful intelligence” (Sternberg 2012). In this view, success of the individual in real-world situations, including interpersonal and intrapersonal knowledge, are weighed just as heavily as the kinds of abstract abilities represented in most standard intelligence tests. Gardner’s theory of multiple intelligences (Gardner 2011) stressed the independence of multiple intelligence components even more heavily; this theory encompasses the view that intelligence is not a unitary construct but instead could be measured as multiple traits or abilities, such as body kinesthetic sense, musical ability, and so on, that are not necessarily correlated. That is, a person could be exceptionally skilled as a musician but not have superior verbal or quantitative reasoning skills and vice versa.

Gardner’s conception of intelligence highlights the potential for confusion between particular skills and general abilities. Should a talented musician or artist be considered intelligent in the same manner that a chemical engineer, mathematician, or neurosurgeon would be considered to be intelligent? Should distinctions be made between different types of skills with some qualifying as “intelligence” and others being considered more akin to “talents”? Both intelligence and talent seem to rely on heredity to a large extent, although talent is more likely to be honed by experience and specific training, and is always highly specified compared to the notion of *g*. Studies of the activation of brain areas during different types of tasks seem to support the notion of separate intelligences to some degree as they show that different areas are activated during different tasks (Hampshire et al. 2012). These recent studies emphasize the fact that the study of human intelligence is really still in its infancy despite being the target of much controversy and interest for many decades.

Researchers have not made explicit attempts to apply the same definitions to the question of animal intelligence, and, given that the topic is controversial in humans, it is clear that determining the intelligence of nonhuman organisms is not a straightforward task. However, there may be stronger agreement with a definition of intelligence that focuses on a general capacity to acquire and apply knowledge among researchers studying cognition in nonhumans. For example, working memory is commonly viewed as an essential component of animal intelligence (Carruthers 2014). Other recent approaches have focused on behavioral flexibility, which is defined as an animal's ability to generate novel behaviors to solve problems and includes components such as inhibition along with innovation (Lefebvre et al. 2013). Whereas innovation represents the likelihood of attempting multiple novel solutions to solve problems, inhibition reflects the ability to withhold responses that may have been beneficial in the past but that no longer prove useful. Individuals may vary in the extent to which they show innovation and inhibition with each component predicting success on different aspects of problem-solving. Behavioral flexibility can be exhibited in traditional tasks, such as reversal of learning set (Roberts 1996), which requires an animal to reverse an earlier learned discrimination, learning the new task more quickly than the original task. Reversal learning, thus, clearly depends upon inhibition to a great degree.

Generalization of knowledge or concepts to novel contexts and stimuli is also a hallmark of intelligence. However, given the recent findings from neuroscience suggesting that different brain regions underlie different tasks designed to assess intelligence in humans (Hampshire et al. 2012), it seems plausible that different types of intelligence may have arisen in response to different environmental inputs for species that face unique adaptive problems. That is, the types of adaptive problems faced by, for example, insects, cetaceans, corvids, primates, and carnivores are likely to be quite distinct, leading to separate sets of adaptive skills and abilities. This fact may call into question the notion of one generalized intelligence factor that could be assessed across taxa.

What Makes An Animal Intelligent?

Along with the challenge of defining what is meant by intelligence in general, research into animal intelligence is plagued by a humancentric bias, whereby researchers often conduct “holy grail” type searches for the presence of abilities in animals that have been deemed potentially unique to humans (Vonk and Povinelli 2006). That is, humans have placed themselves atop an imaginary pedestal based on their capacity for language, tool use, imitation, culture, and theory of mind, thus setting the stage for researchers to commit careers to finding evidence for similar capacities in various other species, sometimes with little regard for whether it makes evolutionary sense for the particular species studied to exhibit the behavior in question. It is tacitly assumed that such evidence would allow for a pronouncement of “intelligence” in the species shown to exhibit it. This kind of anthropocentric focus detracts from a more ethological focus on the ability of each species to adapt to its own unique environment. Do factors that define human intelligence necessarily make sense when defining what makes an animal intelligent? For example, would an animal that spent its day calculating abstract mathematical theorems be more intelligent than the bird that was able to build a sturdy nest out of sight of predators and find food for its hungry nestlings? So, intelligence can be defined as a pattern of behavior that serves the individual in enhancing its reproductive fitness and survival or it can be defined as a suite of cognitive capacities that allow it to perform feats considered to be complex, sophisticated, and generally human-like. Different definitions may be applied within the two broad categories of inquiry identified earlier. That is, researchers may focus on the former when examining individual differences but focus on the latter when performing comparisons between species.

The study of animal intelligence has its origins in Darwin's early fascination with the continuity of the mind across species (Darwin 1898)—a topic that was fervently explored by his successor, Romanes (1882). To what some would argue to be the detriment of unbiased study, the

Aristotelian *scala naturae* or Great Chain of Being was at least partly responsible for the widespread idea of the hierarchy of intelligence, with humans poised atop the scale and species more closely related to humans conceived of as superior in cognitive function to those more distantly removed. Later theorists emphasized the fact that evolution should more accurately be represented as a branching bush than a ladder, with concepts such as parallelism and convergent evolution emphasizing the importance of both similarities and differences in cognitive function in animals both distantly and closely related (Novick et al. 2011). That is, distantly related species may evolve similar solutions to similar or different adaptive problems faced in their evolutionary history. Common selective pressures, such as adapting to live in large social groups (Jolly 1966; Humphrey 1976), may lead to the evolution of traits such as theory of mind and analogical reasoning in animals as diverse as corvids, cetaceans, canines, and primates.

In more recent years, researchers from various fields, such as biology, anthropology, ethology, and psychology, have all been intrigued by the question of nonhuman intelligence and have studied it from vastly distinct theoretical perspectives. Researchers studying animals in the field (e.g., Anthropologists, Primatologists, Ethologists, Biologists, Behavioral Ecologists) have tended to focus on questions of how animals adapt to and solve ecological problems, whereas those studying animals in captivity (e.g., psychologists, biologists, zoologists) have focused on questions of generalized versus compartmentalized learning.

Assessments in Nonhumans

Questions of adaptation concern the way in which an animal's sensory and motor capacities, along with cognitive capacities such as attention, memory, and decision-making, contribute to the organism's everyday functioning. That is, a more successful or skilled individual is better able to find food, mates, maintain and defend a territory, and raise young to reproductive age compared to a

less skilled individual. Organisms will vary in the extent to which particular skills are necessary based on the particular set of environmental and social pressures that they face in their natural environment. For example, birds that nest in colonies must develop the ability to recognize individuals, including their young, whereas birds that are solitary may not need to learn to discriminate their parents from other birds and their young from other nestlings. Birds that cache or store their food over harsh winter months might be expected to exhibit superior spatial memory skills relative to noncaching bird species that live in climates where their preferred food is abundant year-round (Shettleworth 1998). Still, within these species, individuals might vary regarding the extent to which they excel at even species-typical behaviors, although it is likely that the skills most pertinent for survival are hard-wired and instinctive and would not reflect a great deal of flexibility. Thus, flexibility in behavior and the capacity to adapt to novel or changing environments seem a good candidate for something akin to intelligence in nonhumans.

However, most scientists would be unlikely to consider insects more intelligent than mammals that live in more restricted environments (e.g., polar bears, lemurs) despite the fact that insects have likely adapted to the largest number of environments in the largest quantities. There is conjecture that insects will be left to roam the earth long after humans have been wiped off the planet. If the ability of an organism to transform the environment to suit its own needs was considered the ultimate form of adaptation, then surely humans would rise to the top of the list. However, this definition might appear anthropocentric as it targets a specifically human cognitive adaptation. Whereas many species of insect exist in a multitude of habitats, only humans have proven capable of building temperature and climate controlled structures or traveling through air, ground, sea, and outer space. Furthermore, scientists might consider the Giant Panda (*Ailuropoda melanoleuca*) not to be "intelligent" given that it has not adapted well to varied environments and is restricted to an extremely limited diet. Given their dependence on a diet of bamboo, large territories,

and a very limited reproductive window, pandas are critically endangered. It is often suggested that their appeal to humans and human concerted efforts to conserve this species is the only reason that they are not currently extinct. But cognitive tests conducted with pandas have shown cognitive skills, such as memory, categorization, and problem-solving (Perdue et al. 2009). Thus, the two different approaches to measuring intelligence are likely to lead to different conclusions regarding species differences and perhaps individual differences as well.

Psychologists and anthropologists tend to focus on questions of what it is that makes human cognition unique, which may lead to biases in the way intelligence is defined. These scientists typically define intelligence as a general capacity for acquiring information and generalizing learned rules and associations to novel events or experiences. This capacity allows an animal to behave appropriately in the absence of specific learning or associations to each independent event or stimulus. Thus transfer tests, which test the generalization of a learned rule to novel stimuli that share some feature with trained stimuli, have become the acid test of intelligent behavior for comparative psychologists. Transfer based on perceptual features is considered less cognitively sophisticated than transfer based on function or conceptual category or rule. The inference of underlying causal mechanisms that would allow the generalization of a rule or outcome is considered one of the hallmarks of intelligent behavior in humans, and researchers have sought to demonstrate this capacity in many other species with mixed interpretations of the results (Vonk and Povinelli 2006).

The application of these types of tests often necessitate that animals in the laboratory are presented with objects that are foreign to them, thus eliminating the role of associative learning and tightly canalized responding, in order to test their inferences about the function or purpose of the object. Removing the organism from contexts for which responses might be instinctive or canalized allows it to demonstrate insight and inferential reasoning. Researchers can thus disentangle

intelligent behavior from hard-wired and automatic responding (Vonk and Povinelli 2010). Although a behavior can lead to success in natural environments, it may not be considered intelligent by traditional definitions if the animal need not engage in any conscious processing or decision-making to achieve the result. For example, many reflexes are highly adaptive, such as blinking when a foreign object approaches an organism's eye, but the blink reflex is not traditionally concerned intelligent because it occurs without any conscious effort or reflection and is generally present from birth.

Furthermore, similar responses can often occur in different organisms through quite distinct underlying processes. Humans, for example, might comfort an individual who is crying because they understand and empathize with emotions of sadness, which are expressed in a crying counterpart. A feline companion might similarly appear to comfort a crying human by climbing into his/her lap and licking his/her face. But these behaviors might result from the cat's desire for the salt in human tears or recognition of cues that the human is amenable to petting it. Tests of cognitive processes in nonhumans are challenged by the difficulty in unearthing the underlying process for behaviors that, on the surface, seem to align with behaviors that arise from complex cognitive processes in humans – the only species whose underlying thought process is easily accessible to researchers (Vonk and Povinelli 2006). Recognition of such challenges has been identified as “failure of arguments by analogy.” One simply cannot conclude that apparently similar behaviors arise from the same underlying cognitive mechanisms.

Because of the importance of underlying processes or mechanisms that support behavior, psychologists have also examined the process of learning. Animals are assessed for their capacity to learn through the use of learning sets and reversal learning. These tests determine whether organisms apply rules or strategies for learning that transcend the particular stimuli they have learned to associate or discriminate. For example, with categorization tasks, researchers aim to

demonstrate that an animal can extract the features of particular stimuli and form an overarching representation of the category to which they belong. They may use two-alternative forced-choice tests in which animals are reinforced for responding to items from one category and not reinforced for responding to stimuli from another category (Hollaway 1969). In addition to learning which category of items is deemed “correct” and will be rewarded when responded to, the animals might also learn the general task, that is, to extract a correct category or set of features that will result in reward and that will define all pairs of stimuli presented within the task. If researchers reverse the reward associations, the animals should learn more quickly to select the previously unrewarded stimuli in comparison to how long it took them to acquire the initial discrimination, thus demonstrating reversal learning, which reflects the application of a general rule for how to solve such tasks.

Researchers also commonly make use of matching-to-sample (MTS) tests where animals are presented with a sample stimulus and required to select the stimulus from among a set of at least two comparison stimuli that best matches the sample (Harlow 1943). Stimuli can be matched based on perceptual features, such as shape or color, or can be matched on more abstract constructs, such as sameness or differences between sets of exemplars (Bovet and Vauclair 2001; Vonk 2003). Sameness and difference can also be defined in terms of identity or similar features but also in terms of same or different relations, which can be social (Bovet and Washburn 2003) or functional in nature (Bovet and Vauclair 2001) as well. The greater the distance from reliance on perceptual features to the inference of underlying unobservable traits, the more abstract the rule, and, the more abstract the rule, the more intelligent the process is deemed to be (Vonk and Povinelli 2006).

In considering whether a species exhibits intelligent behavior or thinking, it is necessary to find only one member of the species that exhibits such a behavior, thus making it possible to test for capacities with small sample sizes in lab settings.

However, then researchers must confront the risk that animals raised or housed in captivity may not be good representatives of their species, and null results cannot be taken to implicate the failure of a species to have a particular capacity (Vonk and Povinelli 2011). Laboratory studies can, on the other hand, be better candidates for exploring individual differences as individuals can easily be tracked and tested in multiple tasks. Surprisingly, few researchers have attempted to track individual differences in cognitive capacities in members of the same species to identify the possibility of a generalized intelligence factor, such as *g*. Vonk and Povinelli (2011) examined the findings from decades of research with a small group of chimpanzees to determine whether acquisition, transfer, retention, and overall performance were correlated across tasks in different domains (tasks that tapped into social versus physical reasoning processes) and found some evidence for individual differences as well as consistency within individuals across measures. Herrmann and colleagues conducted a large scale study of over 100 chimpanzees and over 100 human children and found evidence for a shared general intelligence that reflected physical reasoning, but a uniquely human social intelligence factor (Herrmann et al. 2010). Currently, evidence for general intelligence factors in other species is lacking. Although progress is underway, it is hampered by the difficulties in obtaining large samples of members of the same species and the time investment required to perform dozens of tests. Furthermore, the issue of comparability of tasks across species that have evolved distinct perceptual and morphological features poses a particular problem for interpreting species differences and for being certain that researchers have tapped into the appropriate tests for assessing individual differences within a species. For example, it would not be appropriate to test species like moles (family *Talpidae*) in a visual discrimination paradigm given their poor eyesight and then conclude that a failure to learn the discrimination reflected poor conceptual ability or that there was no variability in conceptual ability within the species. Imagine if humans were assessed for

intelligence based on their ability to echolocate or to navigate using geomagnetic cues.

Brain size has often been implicated as a measure of intelligence in animals, either with or without accounting for body size. MacLean and colleagues (2014) conducted a large scale project to investigate self-control in representatives of 35 different species. They discovered a relationship between absolute brain volume and task performance. Controlling for body mass resulted in a weaker relationship between brain volume and task performance. These investigators also found that, within primates at least, dietary breadth rather than social group size was a stronger predictor of performance. Recently, researchers have examined problem-solving in a large number of carnivores and indicated a similar relationship between brain size and problem-solving success (Benson-Amram et al. 2016), this time when controlling for overall body mass. However, similar to the MacLean et al. (2014) study, there was little evidence for the importance of social group size or complexity. In future, it will be important to investigate the role of dietary factors in predicting success of carnivores in solving foraging related extraction problems and to present animals with more than a single task to assess ability (Vonk 2016). Sol and colleagues (Sol et al. 2005) have examined the role of brain size in a more naturalistic assessment of intelligence. They found that larger-brained birds adapted more successfully to novel environments compared to smaller brained birds after examining a database of over 600 introduction events. These authors were also able to show that the enhanced success of larger-brained birds could be attributed to increased innovation, which as indicated earlier is one component of behavioral flexibility.

Factors Contributing to the Evolution of Intelligence

The research summarized above highlights the factors that researchers have attended to when determining which species might be considered most intelligent. Two main hypotheses have been

advanced, the social intelligence hypothesis (Jolly 1966; Humphreys 1976) and the technical intelligence hypothesis (Byrne 1997). As labeled, the social intelligence hypothesis focuses on the size and complexity of social groups in predicting cognitive ability, with larger, more complex groups predicting more advanced cognition. The technical intelligence hypothesis instead focuses on challenges faced in foraging, such as the need to find and remember the location of patchily distributed and sporadic food sources and the ability to extract food from defenses. Researchers have sometimes postulated that social complexity might predict skills in specific social domains, whereas foraging challenges may predict physical problem-solving skills, although researchers have also made the case that each factor might promote domain general intelligence. More recently Sol (2009) has revisited the cognitive buffer hypothesis, which encapsulates the notion of environmental variability in general in predicting larger brains, which, in turn, appears related to some aspects of intelligence, as described above. The theory proposes that larger brains result in an increased capacity for gathering, storing, and synthesizing information, related to the idea of domain general intelligence, and that this increased capacity may lead to a broader range of new or modified behaviors, which increase the probability of survival in complex and constantly changing environments.

Convergent Evolution

More recent approaches have steered researchers away from the rigid assumptions of the past, which clung to the notion that animals advanced in cognitive complexity along a continuum leading to humans atop the imagined evolutionary ladder. Animals were assumed to exhibit greater cognitive complexity and thus intelligence, with shorter phylogenetic distance from humans. However, researchers have unearthed great behavioral diversity and cognitive complexity in animals ranging from honeybees to corvids and cetaceans. Indeed corvids and canines have surpassed great apes in some kinds of cognitive tasks, supporting the point

that it is important to focus on tasks for which animals might be expected to face adaptive problems in their evolutionary history. Given the increased breadth in species of study within comparative psychology in the last decade, researchers more readily embrace the notion of convergent evolution – animals that are distant relatives and who have adapted to quite discrepant ecological niches might still evolve comparable cognitive abilities to solve problems within their own niche.

Conclusion

In the end, it appears necessary to consider how well animals have adapted to solve the particular kinds of adaptive problems that they will face, with a particular emphasis on flexibility to change, which will increase the odds of both individual and species survival, when determining which species and which individuals are most intelligent. As Vonk and Povinelli (2010) noted, a starting point is to observe an animal's natural behaviors in the wild, but the laboratory may be more carefully controlled to rigorously test hypotheses about how and why specific behaviors may have evolved and how they might be altered under specific conditions. Researchers can then distinguish between behaviors that are plastic and those that are rigid and canalized. Flexible and malleable behaviors will allow an individual to adjust and adapt to an ever-changing, unpredictable environment, which is argued here to be the true mark of intelligence (Sol 2009). By combining field and laboratory approaches knowledge of what animals actually do in their natural environments can be used to further probe what they are ultimately capable of learning when taken out of those comfort zones.

Non-human Leadership

Definitions

Leadership occurs when an individual or subset of individuals within a social group or aggregation has a disproportional influence on the behavioral outcomes of conspecific members within the group regardless of how this effect is achieved.

Introduction

Leadership is ubiquitous within animal societies, occurring when one individual or subset of individuals, the leader(s), exert(s) a disproportional influence on the behaviors of others (followers; Smith et al. 2016). Leaders emerge in non-human groups or aggregations of animals regardless of the how this influence is achieved (Smith et al. 2016). Within non-human animals, most research has focused on collective movements during groups travel (e.g., Reynolds 1987; Boinski and Garber 2000). More recently, the concept of leadership has been extended to also explain collection action within the domains of foraging, conflict resolution and between-group conflicts (Smith et al. 2016). Here, I synthesize what is known about leadership in non-human societies by providing a brief overview of seminal work within domain of group travel and recent developments in this domain of leadership, discussing the ways that leadership permeates into other domains within non-human animals, and then comparing these patterns of leadership in non-human societies to those in human societies.

Collective Movements During Group Travel

Collective movement occurs when two or more individuals maintain spatial proximity while travelling together to a new location (Petit and Bon 2010). Pioneering studies on collective behavior set out to understand the basic rules explaining coordinated, large-scale patterns of movements by aggregations comprised of hundreds of insects, fishes, starlings or hooved migratory animals traveling together in a seemingly coordinated manner. Whereas it was once hypothesized that such aggregations might rely upon a centralized authority, seminal work by Reynolds (1987) proposed an alternative model suggesting that instead complex patterns of swarming, shoaling (schooling), flocking and herding behaviors may be explained by patterns of localized leadership and followership. This parsimonious mathematical model relies upon the following simple rules by which individuals adjust their movements based on information gathered from their local neighbors' movements and positions. For example, flocks of birds coordinate collective movements by following three simple rules: velocity matching, flock centering and collision avoidance. Flocking therefore emerges when an individual bird (follower): (i) matches the speed of nearby flockmates (localized leaders), (ii) maintains close spatial proximity to nearby flockmates, and (iii) avoids colliding into nearby flockmates. These powerful insights have prompted a large body of research confirming these patterns and this model is the most-widely accepted view of how leaders emerge in these contexts. For example, desert locust nymphs (*Schistocerca gregaria*) also rapidly transition from disordered movements to form large swarms comprised of coordinated movement patterns during marching behavior (Buhl et al. 2006).

Extensive studies documenting how and why non-human vertebrates travel in groups suggests that socially-complex mammals also follow simple rules (Boinski and Garber 2000). That is, as in other gregarious animals, social carnivores, birds, and primates living in closed social groups

also seem to adhere to simple rules to navigate group travel from one location to another; these group-living animals often accrue individual fitness benefits, such as reduced predation risk, group acquisition of shared resources and group defense against neighboring social groups from following leaders (Boinski and Garber 2000).

Group travel that requires all group-mates to choose between collectively moving to a new location and remaining together in their current location represents a 'consensus decision' (Conradt and Roper 2005). Because travel decisions often have fitness consequences for all participants, leaders may emerge to resolve consensus decisions that impose conflicts of interest (consensus costs) requiring all members to settle on a single direction, timing or destination of group travel (Conradt and Roper 2005). For groups in which only a few individuals have pertinent information, such as about the location of a food source or a migratory route, patterns of leadership often emerge even in the absence of signaling by leaders, without any active coercion on the part of the leader, and even when followers lack information about which individuals possess information (Couzin et al. 2005; Smith et al. 2015). Importantly, Couzin et al. (2005) showed that only a small proportion of the informed individuals (leaders) are required to lead during collective movement.

Although pioneering models of leadership based on short-term studies in non-human mammalian societies indicated that one or few dominant individuals may consistently occupy leadership roles, more recent work drawing from long-term studies based on recognizable individuals suggests that leadership roles tend to be flexible and shared within groups (Smith et al. 2015). Specifically, Smith et al. (2015) joined others in showing that attribute-based leadership is the most common pattern among mammals, with an individual's motivational state, sex, relative social status and age class at the time of group travel profoundly shaping his/her leadership (or followership) during the group travel (Smith et al. 2015).

Collective Acquisition and Distribution of Food

Although most research to date focuses on leadership during collection movements, leaders also emerge within the acquisition and distribution of foraging (Smith et al. 2016). Most notably, leaders emerge in gregarious species, such as in the social carnivores (carnivorans) when individuals cooperate to acquire energy-rich food items that they would be unable to capture or locate on their own. For example, female elders within groups of African lions, Verreaux's safakas (*Protopithecus verreauxi*), killer whales (*Orcinus orca*) and spotted hyenas all typically enlist more followers than do young, naïve individuals in collective foraging presumably because they possess the greatest local knowledge (reviewed by Smith et al. 2015). Orcas are noteworthy because post-reproductive (menopausal) female resident killer whales lead collective foraging efforts in search of salmon, particularly when food is in low abundance and to promote the survival of their sons who lack local ecological knowledge (Brent et al. 2015). Following the acquisition of food, leadership roles vary widely across taxa. For example, even within carnivorans, lionesses equally distribute food within their egalitarian societies whereas high-ranking adult females control priority of access to food resources within their female-dominated societies (see: Smith et al. 2016). Nonetheless, as in the context of collective movements, leadership also appears to be attribute-based. That is, to the extent to which it has been investigated, those individuals with local knowledge tend to emerge as leaders within the foraging domain.

Leadership During Within and Between-Group Conflicts

Lastly, as in human societies, non-human leaders often emerge to settle or win conflicts within or between groups (de Waal 1990). Because conflict is potentially costly to individuals, natural selection favors mechanisms, such as the emergence of leaders, that mediate conflict resolution within

groups (de Waal 1990). Moreover, because the outcomes of between-group competition often have large fitness consequences for members of a social groups, such as determining the size of a territory containing key resources, natural selection often favors those individuals who join forces during between-group conflicts. Both during conflict resolution within groups and during warfare associated with between-group conflicts, leadership roles in mammalian societies are much more concentrated (less shared) and leaders exert more power than in contexts when conspecifics are simply traveling from one area to another or engaged in collective foraging (Smith et al. 2016). Future studies are needed to elucidate whether this pattern extends to other taxa beyond mammals.

Within these conflict domains, leadership roles also tend to be occupied consistently by one or a few dominant individuals who exert the most power within their societies. For example, among non-human primates, high-ranking apes and monkeys most often take the lead in resolving within-group conflicts through reconciliation; dominants often lead in consoling their former opponents after fights (De Waal 1990). Within spotted hyenas (*Crocuta crocuta*), high-ranking adult females also emerge as leaders, tending to emerge most often at front lines of between-group conflicts and to intervene most often during within-group conflicts (Smith et al. 2016).

Conclusions

Overall, despite the enormous range of taxa across the animal kingdom for which individuals emerge as leaders, common rules appear to explain patterns of leadership within and across leadership domains. Together, studies of collective movements indicate that attribute-based leadership is often shared within groups or aggregations and that patterns on non-human leadership is best explained by simple rules requiring localized decision-making and only a few informed leaders. Thus, despite the enormous disparities in the scales over which animals collectively move and the vast differences in presumed cognitive

abilities across taxa, similar rules appear to explain collective movement decisions, suggesting that general principles may underlie leadership during collective movements.

Although most research to date has focused on leadership during collective movements, leaders emerge across multiple domains within loose aggregations of animals and close social groups ranging from insect swarms to pods of killer whales. Leaders disproportionally influence the collective behaviors of others, determining the direction of travel, foraging decisions and the outcomes of conflicts within and between groups. Synthesis of current data suggests that leadership roles are particularly flexible during group movements, as dictated by current state variables such as age and reproductive status, but that leadership roles are least shared and leaders wield the most power in contexts involving resource acquisition. Indeed, preliminary data suggest that this is also the case for small-scale societies of humans as well (Smith et al. 2016). Moving forward, workers should draw upon the comparative framework of Smith et al. (2016) to evaluate the generalizability of these patterns of human and non-human leadership across the domains of group movement, food acquisition, within-group conflict mediation and between-group interactions. Within an evolutionary framework, workers studying leadership more broadly will gain new insights about the importance and universal principles of leadership that together give rise to collective behaviors in gregarious species of animals, including ourselves.

Definition

Study of the physical, cognitive, and behavioral development of nonhuman primates, particularly in reference to human cognition and development. Emphasis is placed on understanding similarities and differences between all primate species to better understand the evolutionary origins of these species and their abilities.

Introduction

The study of nonhuman primates (NHP) can include a wide variety of species that vary greatly in their similarity to human development and psychology. Primates include (in order of ascending genetic relation to humans): New World Monkeys, such as capuchin and howler monkeys, Old World Monkeys, such as macaques and baboons, and the Great Apes (GA), orangutans, gorillas, bonobos, chimpanzees, and humans. This entry will focus on Great Apes as they are genetically closest to humans and used most frequently for understanding the evolutionary origins of human physical and psychological development. Nonhuman Great Apes share many physical and psychological traits with humans and human development but also display substantial differences from human abilities. One might be inclined to assume that in the cases of differences with humans, the other Great Apes are deficient in ability. However, in many cases, specific abilities of nonhuman Great Apes exceed human capabilities, suggesting some interesting

differences in selection pressures. The study of nonhuman primates is a critical piece of the puzzle in understanding evolution as a process in general, primate cognition and behavior, and human psychology and development.

Physical and Brain Development

GA prenatal timing is remarkably similar to humans. For example, the prenatal gestation period for humans is 266 days on average, with chimpanzee (~235 days), gorilla (~250 days), and orangutan (~260 days) (Martin 1981). However, once born, the timing and stages of physical development differ greatly. Chimpanzees move through three distinct developmental life stages, infancy, juvenile, and adulthood. The end of infancy is marked by the cessation of breastfeeding, around 4–5 years, and the end of juvenility is marked by sexual maturity, around the age of 12. Humans, however, have five distinct developmental life stages, Infancy, Childhood, Juvenile, Adolescence, and Adulthood. Human infancy, like that of chimpanzees, is marked by the cessation of breastfeeding. Childhood is a human specific life stage marked by a period where solid foods are eaten but self-sufficiency and survival are impossible. Juvenility in humans is the period between the emergence of adult teeth and the onset of puberty. Adolescence is the period between the onset of puberty and the achievement of consistent reproduction, occurring around the age of 15–16 years and marks the beginning of biological adulthood.

Most noteworthy about comparisons of human physical development with NHPs is the addition of Childhood and Adolescence as life stages and delaying the onset consistent reproductive viability. Given that the process of natural selection ultimately depends upon an individual reproducing, it seems odd that natural selection would favor delaying the ability to create offspring until such a comparably old age. A number of factors likely led to this evolutionary change in human development: humans have large heads relative to body size thus requiring developmentally premature birth when compared to other species, the social complexity

of human life requires time for learning, observation, and cognitive development, and allowing humans time to flexibly incorporate environmental cues into their life-history strategies (Bjorklund and Ellis 2014).

Humans and NHPs have very similar brains; specifically, they have a much larger prefrontal cortex than other animals, the area of the brain responsible for complex cognitions such as critical thinking, cognitive flexibility, and decision-making. Humans have, on average, the largest brains relative to body size among the GAs. However, many believe that increases in white matter connectivity (neural connection within the prefrontal cortex and those emanating to other brain areas) are chiefly responsible for the advanced cognitive feats performed by GAs and even more so the complex abilities that often set humans apart from other GAs (Smaers 2013).

Memory

Human memory is conceptualized as a flexible system with numerous interacting components that serve multiple purposes. Long-term memory (LTM) is the storage and retrieval system that allows for remembering information over the course of hours to years; this is typically what is meant when the term “memory” is used in everyday life. Short-term memory (STM) helps remember information in short time frames on the order of seconds or minutes. Finally, working memory (WM) is the system that keeps information activated in the thoughtful and aware mind in order to perform actions with that information; when you are currently “thinking about something” that information is said to be active in working memory. Decades of research have found these systems to be interactive while also cognitively and neurologically separate. Information that humans can remember can further be divided by its qualities or content. Episodic memories are those that retain a personal quality from a specific time and place (e.g., I remember my grandmother making me homemade donuts on my 9th birthday), whereas semantic memories are simply information (e.g., Alexander the Great was Macedonian).

There is no doubt that NHPs, especially GAs, possess all of these systems and use them in very similar ways to humans. GAs remember family members and social others, the locations of food sources, and how to engage in complex tasks such as tool use. In fact, there is evidence that chimpanzee WM has a greater capacity than human WM. However, debate exists about whether any GA memories can be said to be episodic and include a “personal” component rather than simply an informational component (Sellers and Schwartz 2013). Many have come to call their memories “episodic-like” highlighting the fact that these memories share some characteristics with human episodic memories, but it is experimentally difficult to confirm their exact episodic nature given the limits of communication between humans and GAs.

Developmentally, it is very likely that GA memory over the lifespan follows a very similar course to humans. Memories in infancy are probably not episodic nor semantic in nature, they are purely sensory. However, there is evidence that human children as young as 2 months display memories with some episodic qualities, such as context-dependency (Rovee-Collier and Dufault 1991). With age, LTM, STM, and WM all begin to function in rudimentary ways, with capacity and accuracy increasing with age. Human memories are undoubtedly episodic by the age of 1, as they can generalize knowledge learned in one setting to another (Learmonth et al. 2004). However, little definitive information is known about the exact nature of NHP memory development in early life. It is very difficult to study young primates for a number of reasons, and much must be inferred from day-to-day behavior, leaving many questions unanswered.

Language and Communication

All NHPs engage in communication, both verbal and nonverbal, with social others. Obviously, humans have a natural mastery of complex, representational language that far surpasses the capacity of all other NHPs. However, NHPs can engage in quite sophisticated and varied

communication, as evidenced by chimpanzees' use of different vocal calls to signal different types of danger (e.g., a certain call is used to alert for danger on the ground while a different call alerts for danger in the air or trees).

The most famous developmental-comparative case of language between humans and nonhuman GAs is the case of Kanzi, a bonobo raised in captivity from birth. Kanzi, currently 35 years of age and living at the Ape Cognition and Conservation Initiative in Des Moines, Iowa, exhibits the most sophisticated language abilities of any known NHP. He is able to communicate using lexograms, complex and abstract symbols that stand for physical items and actions. GAs cannot make human vocalizations due to differences in their vocal tracts. One likely reason for his superior abilities is his early exposure to language; his adoptive mother, Matata, was being trained to learn lexograms when Kanzi was young. This early exposure seems to have provided Kanzi with a developmental advantage in language abilities. This can be viewed as analogous to Noam Chomsky's idea for an early critical period in humans when language is most efficiently learned. There is some debate within the scientific community about whether Kanzi's abilities can rightly be called representational language, but even if they fall short of this high bar, his abilities are no doubt impressive and important to our understanding of the evolution of language.

Social Cognition

Social cognition is a broad construct encompassing the cognitions and behaviors used to interact with or think about others and situations involving them. The cognitive ability most closely associated with social cognition is Theory of Mind (ToM). ToM is the ability to think about the contents of another person's mind (e.g., I know that Johnny knows the answer to the trivia question). This ability is important for predicting the behavior of others based on their held beliefs and personal desires so that an individual can formulate appropriate responses and behaviors in reference to this other person. For

example, if I am eating dessert with Erica and I know that she loves ice cream I can give her the ice cream while I eat the brownie. However, I can also purposefully give her the brownie to be mean if I know that she thinks badly of me and has been gossiping behind my back. These decisions rest upon ToM.

Human children typically achieve explicit ToM around the age of 4, with sophistication and proper use increasing with age. There is some debate that perhaps these cognitions occur earlier; however, there is no debate that by 4 years of age children are complex social thinkers who can make appropriate assumptions about the minds of others. Children use this ability to imitate each other and adults in order to learn complex tasks, skills, and appropriate social behavior. They form complex friendships, social groups, and social hierarchies at a young age. Young GAs also engage in observation and imitation of adults, particularly tool use (i.e., fishing for termites or cracking nuts with stones). They also form social groups, understand the adult social hierarchy, and behave differently towards relatives and nonrelatives. These behaviors suggest that young GAs may have social cognitive abilities comparable to those of young human children.

Adult GAs certainly possess complex social cognitions: they can enlist humans to help them in cooperative tasks, can make assumptions about the desires of a human and assist in completing a task the human cannot do alone, and appear to understand that eyes are a source of another individual's ability to gather information (Tomasello and Call 2010). However, aided by language and communication abilities, human adults achieve much more sophisticated social cognitions and collaborations than GAs.

Conclusion

NHPs and humans share many abilities and characteristics that evidence their common evolutionary history and genetic similarities. However, differences abound in both the developmental course of these abilities and in their final adult complexities. However, humans faced

evolutionary pressures that increased the length of childhood and supported an intricately connected frontal cortex, leading to complex, self-referent memory, representational language, and incredibly sophisticated social cognitions.

Definition

Aggressive interactions between two or multiple conspecifics from different social groups in primate species usually lead to the death of at least one of the contenders and to fitness advantages to victors.

Introduction

Observations of between-group aggression and killing exist for a wide range of primate and non-primate mammals. Such phenomena occur in different forms, such as coalitional efforts, or independent and individual attacks (i.e., dyadic aggression), and targets may be individuals of any age. This entry will review the current literature on lethal intergroup aggression in nonhuman primates, describing evidences of adaptive value for aggressive interactions and especially killing between groups, in contrast to hypotheses that rely on the concepts of environmental mismatch, trait neutrality, or maladaptation to explain such phenomena. Even though this review will cover reports of lethal aggression between groups which overall also support adaptive hypotheses in

multiple species, special attention will be given to chimpanzees, considering the more intense research effort for this clade and an abundance of aggression descriptions, which permit detailed analyses of evolutionary predictions.

Review

Early theories considered intergroup killings to be exclusive of human societies living in complex political systems such as nation-states. However, observations with chimpanzees (*Pan troglodytes*) during the 1970s at Gombe, Tanzania (Wilson 2013), indicated that lethal attacks across communities were not uncommon. It is now estimated that intergroup killings in chimpanzees exhibit rates that are comparable to those in small-scale human societies, and higher than in modern, industrialized societies (Wrangham et al. 2006). The implications of these reports for understanding the origins of violence and warfare in human societies were met with both skepticism and opposition. According to some researchers, intergroup killings should not be considered a natural trait of the species, but rather a pathological social behavior associated with human interference factors such as ecological disturbance, the size of the protected area, and food provisioning in field sites. Such view is now currently known as the *human impact hypothesis* (HIH; Wilson et al. 2014). Another concern is that human “warfare” is a term sometimes arbitrarily reserved for violent conflicts killing at least 1,000 individuals, and chimpanzee conflicts have never been observed to achieve that dimension.

Alternatively, although the *adaptive strategies hypothesis* (ASH) acknowledged that human activities could not adequately explain the occurrence of lethal encounters, factors such as the number of males in a community and population density were seen as better predictors than human disruption. It is important to note that the HIH does not lead to the prediction that consistent differences would exist in between-group warfare based on the location of the communities (e.g., East–West), the age and sex of attackers and victims, or any variation across species (e.g., bonobos–chimpanzees),

beyond the direct effects of human impact. The ASH, on the other hand, leads to the prediction that natural tendencies for aggressive interactions are exhibited in different levels in different populations, sexes, and life history stages in consistent ways. Fifty years of observations, with 152 cases of intergroup killings reported for chimpanzees and bonobos across East and West Africa, suggest that a model presenting predictors associated with HIH was around seven times weaker compared to models accounting for the number of males and population density, both of which are predictors that are part of ASH (Wrangham et al. 2006; Wilson et al. 2014). From these studies, it is possible to conclude that these intergroup killings (1) exhibit design features that indicate a non-random distribution for characteristics of aggressors and victims, (2) occur in a predictable and organized fashion, (3) are enacted by individuals in sociodemographic categories which are most prepared for, and which would mostly benefit from, intense competition, as is detailed below. Importantly, victims are mostly unrelated to the attackers, in line with expectations from the Inclusive Fitness theory; and the victims and the attackers are mostly males, in line with sexual selection hypotheses.

The inherent costs associated with lethally attacking another individual pose the problem of how this behavior is maintained across chimpanzee communities. According to the imbalance of power hypothesis, intergroup killings would be expected under conditions favoring a maximum cost for the victim and a minimum risk for the attackers. As a supporting example, in the Taï Forest, Côte d’Ivoire, small parties of 1–3 males tend to avoid any direct engagement with adversaries, medium parties containing 4–6 males investigate more actively the territory, and larger parties with 7–9 males pursue physical contact with victims (Boesch 2003). Across chimpanzee communities, intergroup attackers and killers outnumber the targets by a range of 3–9 aggressors per target.

Playback experiments have also demonstrated that chimpanzees in the company of larger parties tend to approach speakers playing the vocalizations of rival males (Wilson 2013). The strategic nature of this behavior has also been demonstrated

based on differences between patrolling (collective travel to the fringes of the territory) and other activities (foraging). Raiding parties spend less time feeding during patrols and more time traveling. Moreover, at the time of the incursion, invaders combine long travel sprints with short rests, periods where they are attentive to cues from members of the rival community. Such organized behaviors further suggest that attacks are not spurious phenomena but rather part of the behavioral repertoire of the species.

Some of the hypothesized functions of intergroup attacks include acquisition of females, territorial expansion, and defense of resources. Supporting this, for example, female chimpanzees in the Taï forest sometime copulate with the attackers within the fringes or their territory (Boesch 2003) or permanently disperse into the group of the attackers (Wilson 2013). Lethal intergroup aggression presents additional fitness benefits to the invaders. Females from invading groups exhibit heavier body mass and shorter interbirth intervals, demonstrating that raiding males improve the reproductive conditions of females and consequently their own, not only by defending the territory but by expanding it (Williams et al. 2004).

Furthermore, intergroup killings in chimpanzee present a median of 271 per 100,000 individuals per year, a rate within the range estimated for human intergroup conflict in small-scale societies (foragers: 164 per 100,000 per year; horticulturalists and pastoralists: 595 per 100,000 per year; Wrangham et al. 2006). Thus, by systematically eliminating lone individuals, attackers are able to reduce the size of rival groups, making them more vulnerable to future attacks. The disappearance of communities such as Kahama (Gombe) or the K-group (Mahale) demonstrates the cumulative effect of such raids (Wilson 2013).

As in other forms of cooperation, the risk of free-riding is a potential destabilizer for collective, organized lethal aggression. Hence, by refusing to participate in any raid, freeloading males may obtain fitness benefits though the group without incurring significant costs. However, analyses with males at Kibale detected a positive relationship between the likelihood of participation,

mating success and the relationship closeness between participants, as measured by the time spent grooming (Watts and Mitani 2001), suggesting that compensating individual fitness benefits exist for those who engage in these intergroup aggressive efforts.

Territorial species living in societies displaying fission-fusion dynamics are more prone to intergroup lethal aggression (Aureli et al. 2006). However, the degree of cohesion and dispersion should not be solely considered as a risk factor. Due to a lower intensity of within-group competition and a higher risk of predation, groups living in the Taï forest have been found to be more cohesive with respect to Eastern communities. This socioecological context provides a protective factor for potential victims. Thus, by decreasing the distance between individuals, lone targets are able to be rescued by other members of the group that may be close to the attack site.

Primates living in fission-fusion societies, such as spider monkeys (*Ateles geoffroyi*; Aureli et al. 2006), have also been observed to form small parties of 3–4 males and invade the territory of competing groups. Moreover, intruders encountering rivals (range 1–3 victims) have been reported to chase the victims. However, there are no reports of intergroup killings as with chimpanzees. Importantly, other primate species exhibit both coalitional and dyadic lethal aggression against individuals from other groups. Red colobus monkeys (*Procolobus badius*) and diana monkeys (*Cercopithecus diana*; Watts et al. 2006) for example, can form small coalitions and kill rivals.

Recently in the Mawas Reserve, Indonesia, a coalitional attack by a male and a female orangutan led to the death of another female, despite the interventions of another male during the attack (Marzec et al. 2016). Only rare evidence of coalitional killings has been described in mountain gorillas (*Gorilla beringei*). In Karisoke, Rwanda, roving males sometimes clash with resident males, and even though the vast majority of these interactions are nonfatal, rare killings have been described (Rosenbaum et al. 2016). In the case of white-handed gibbons (*Hylobates lar*; Palombit 1993), an invading

individual was seen to be lethally wounded by another male. These observations, however, do not approach the mortality rates observed in between-group conflicts in chimpanzees, suggesting that characteristics particular to the socioecology of this species have selected for stronger intergroup competition.

Coalitional lethal aggression against vulnerable lone individuals has also been described in nonprimate species (Watts and Mitani 2001; Watts et al. 2006), including grey wolves (*Canis lupus*), African lions (*Panthera leo*), cheetahs (*Acinonyx jubatus*), and spotted hyenas (*Crocuta crocuta*). In some species such as grey wolves, the mortality rate due to intergroup conflict may reach considerable proportions, demonstrating significant parallelisms with lethal interactions present in nonhuman primates.

Conclusion

Intergroup lethal conflict can be classified as either coalitional or dyadic aggression. Chimpanzee data clearly demonstrate that intergroup killings are not an outcome of human disruption, but rather an emergent phenomenon based on socioecological features including population density, and the number of males per community, with adaptive consequences. Similarly, intercommunity killings display consistent sociodemographic patterns in that males are more likely to be both aggressors and victims, Eastern communities have higher intergroup lethality rates than Western populations, and chimpanzees have higher intergroup lethality rates than bonobos. Patterns of patrolling and lethal attacks have also been found to be strategic, suggesting adaptation. Raiding individuals spend less time foraging and more time travelling into the territory of rival communities. Similarly, lethal attacks occur based on an attackers/victims ratio. Invaders obtain fitness benefits, including attracting new females, inducing shorter interbirth intervals, and acquiring resources.

Several other anthropoid primate species have also been observed to engage in intergroup lethal aggression, however the mortality rate due to conflict is considerably lower than that of

chimpanzees. Still, these occurrences as well as observations in various carnivorous species disconfirm previous hypotheses considering intergroup lethal aggression to be either adaptively neutral or maladaptive, or a contemporary phenomenon exclusive of complex human societies.

atmosphere (Schmidt-Nielsen 1972). However, this is not the case for all walking animals. For instance, spiders lack the muscular structure to extend their legs so they fiddle with their blood pressure to do so, and worms burrow through the dirt using bodily chemicals and muscle contractions (Schmidt-Nielsen 1972). This entry will summarize some of the more common forms of locomotion and specific movements of nonhuman species.

Nonhuman Primates: Species Typical Movement

Synonyms

Brachiation; Flying; Running; Swimming; Walking

Definition

Unique ways in which different animals engage in locomotion.

Introduction

From swimming to flying, there are a plethora of different movements that are specific to certain animal types and their environments. Animals have specifically developed bodies that allow them to navigate their natural environment. For example, fish have slim bodies that allow them to cut through the density of water, with a natural buoyancy to keep them from sinking to the bottom (Schmidt-Nielsen 1972). Birds are slender with the need to carry their weight against a low-density atmosphere. Walking animals thrive in environments that contain a high-density platform upon which to walk through a low-density

Brachiation

Brachiation is the specific movement or extending and swinging of the upper limbs as a means of moving one's body (Turnquist et al. 1999). This movement is apparent in both human and non-human primates. We see this movement when we watch children on the (aptly named) monkey bars on playgrounds (Turnquist et al. 1999). This swinging motion from bar to bar – in which a child holds one bar and swings his/her weight to a second bar on which to grab – is brachiation. Although humans can engage in brachiation, it is not an efficient form of movement for them. Brachiation is usually exhibited as a form of regular movement by smaller nonhuman primates, such as monkeys and lemurs (Turnquist et al. 1999).

Grip

The hands of primates are used for many things like scratching, pulling/pushing, grasping/gripping, feeding, and grooming (Pouydebat et al. 2011). In both human and nonhuman primates, there are two broad classifications of grip – power grip and precision grip. Power grip refers to instances in which an animal grasps an object between its thumb and palm, so that the object is firmly secured in the palm of the hand (Pouydebat et al. 2011). An example of this would be the way a human grasps a bottle or a baseball. In non-human primates, power grips are what aid the animal in brachiation as it is how the animal can exert enough force to hold on to branches while moving (Pouydebat et al. 2011).

Precision grip refers to when animals use the tips of their finger(s) and thumb to hold an object (Pouydebat et al. 2011). When engaging in precision grip, the object being held does not get placed firmly against the palm. Precision grip is often utilized to hold small individual objects, such as a single berry or grape. Precision group is usually used to hold objects that are so small and lightweight that the added force of holding it against the palm is not necessary (Pouydebat et al. 2011).

Walking and Running

Every legged animal possesses a similar mechanism involved in locomotion. This mechanism, known as leg stiffness, is the measurement of peak ground force to peak leg compression in a stride (Shen and Seipel 2015). SLIP or *spring-loaded inverted pendulum* is the model of locomotion that looks at leg stiffness as a mechanism, which illustrates the similarities between different types of locomotion like hopping and walking (Shen and Seipel 2015). The SLIP model postulates that most legged animals have a spring system of locomotion which allows an animal's individual leg movements to propel it forward. Imagine an animal in stationary standing position. As the animal begins to lift its leg to take a step, the SLIP model is utilized to measure the arch of the leg and the pressures surrounding it all the way until the animal is standing again or taking another step. This arching movement is said to look on paper like a pogo stick springing forward (Shen and Seipel 2015). At each step there are different pressures between the leg, the bend of the knee, and the ground (Shen and Seipel 2015).

Swimming

Fish are special creatures as their movement through a dense medium forces them to be streamlined in shape (Schmidt-Nielsen 1972). This streamlining refers to the elongated shape that deflects the atmosphere smoothly around the fish. This allows the fish to move the water around its body as smoothly as possible, decreasing the caloric expenditure of swimming by moving parts of

their body in a manner that utilizes drag to create propulsion (Schmidt-Nielsen 1972). The two main types of propulsion – anguilliform propulsion and carangiform propulsion – are utilized by different aquatic species. For instance, eels engage in anguilliform propulsion, which is a form of propulsion in which the animal uses its entire body to move forward (Schmidt-Nielsen 1972). Species that use carangiform propulsion, such as sharks and salmon, use the movement of their tail fin to generate propulsion (Schmidt-Nielsen 1972).

Conclusion

Locomotion takes many different forms, each of which is specific to certain animals and the atmosphere of their natural environment. This entry focused on multiple different mediums of motion – swimming, walking, grip, and brachiation – to illustrate how species adaptation to an environment can dictate the type of movement in which that species engages. For instance, animals adapted for land living – such as primates – do not swim as efficiently as animals like fish that have adapted for water living. The evolution of environment-specific locomotion has allowed every species to better navigate and survive in their natural environment by allowing them to search for food, evade predators, and seek shelter from other environmental hazards. However, every type of locomotion utilizes a complex process of muscular movement and metabolic activity and therefore should continue to be researched.

Definition

Aggressive conflict between individuals within a group or community in nonhuman primate species, involving violent interactions, in certain circumstances leading to death of one party and fitness advantages to aggressors.

Introduction

Intragroup killings are a common phenomenon in primate species. Whereas attacks among adults have been thought to be selected due to the benefits collected by the assailants such as eliminating rivals, gaining access to material and social resources, and ascending in rank, the evolution of infanticide has mainly been attributed to males restarting the ovarian cycle of lactating

females and copulating with them. Furthermore, other adaptive hypotheses interpret infanticide as means of acquiring and retaining mates, eliminating competitors, removing the genetic presence of rivals, and rising in the social hierarchy. Some of the risk factors associated with male infanticide across primate species include a slow life history, the absence of alloparents, the type of social structure, and the prevalence of male take-overs. This review will cover the empirical evidence supporting the adaptive nature of different forms of intragroup killings in primate species.

Review

Similarly to descriptions of conspecific killings due to intergroup attacks, intragroup killings across primate societies have been hypothesized to be associated with various fitness benefits. Primatology researchers have tested them with multiple species, especially in anthropoid primates. For example, in spider monkeys (*Ateles geoffroyi ornatus* and *A. g. yucatanensis*), intragroup killings have been attributed to a male-biased sex ratio producing an increase in male competition (Valero et al. 2006). In capuchin monkeys (*Cebus capuchinus*), rivalry for occupying high ranks (or rank reversals) in hierarchy, as well as attempted expulsions from the community, are considered to better explain violent deaths. Despite the fact that muriquis (*Brachyteles arachnoides*) display low levels of within-group competition, the killing of an old male demonstrates that even tolerant species may resort to violent behavior to eliminate conspecifics due to conflict escalation (Talebi et al. 2009).

However, originally, intracommunal killings were thought to be the product of captivity (e.g., Arnhem Zoo, the Netherlands; reviewed in Watts 2004), with victims unable to flee the scene. This perspective was challenged when cases contrary to this hypothesis were described in wild chimpanzee (*Pan troglodytes*) communities in Uganda and Tanzania (Ngogo, Sonso, Mitumba, and the M-group; Fawcett and Muhumuza 2000). Similarly to the cases of intergroup killings, these attacks were considered by some to be maladaptive. However, rank upheavals, unequal sex ratios, and the elimination of

mating competitors appear to be some of the adaptive problems underlying this behavior.

Within-group victims of attacks usually occupy a low rank in the hierarchy (Watts 2004). The imbalance of power hypothesis, describing a decrease in the risk for the aggressors due to the collective nature of the attack, has also been considered a factor affecting the likelihood of within-group killings. Thus, by targeting a defenseless individual, coalitions of males reduce any risk to themselves, obtain benefits such as protecting their ranks in the hierarchy, and increase their mating opportunities.

Whereas adults and adolescent males had a higher mortality rate due to intercommunal aggression compared to juveniles and infants in chimpanzees, these were more frequently the victims of intracommunal aggression. The primatological literature supports this pattern, with most hypotheses and studies examining the occurrence of infant killings within groups, rather than adult deaths. As such, much of the research examining the adaptive functions of intragroup killing focuses on infanticide, as reviewed below.

Infanticide has been observed in at least 51 primate species. However, despite its ubiquity, infant killings do not occur at random. Targeted younglings are fully unrelated or genetically distant to the attacker, and the identity of the attackers is biased to one of the sexes. Thus, whereas in rodents most of the perpetrators are females, in primates, unrelated males have been found to be mostly responsible. Among some of the functions of male infanticide, observations in patas monkeys (*Erythrocebus patas*) and gray langurs (*Semnopithecus entellus*) suggest that by targeting the offspring of rivals, males eliminate future competitors and remove the genetic presence of the rivals in the group. In other species such as purple-faced langurs (*Trachypithecus vetulus*), infanticide increased the opportunities of gaining access to limited resources. Meanwhile, in chimpanzees (*Pan troglodytes*) and mantled howler monkeys (*Alouatta palliata*), infanticidal males decreased the coalitional power of competitors. Observations in gray langurs also found a relationship between infanticide and rank acquisition.

Other hypotheses have also considered the use of infanticide as a strategy for mate acquisition and mate retention. Thus, by killing the offspring of a female, males demonstrate a lack of protective abilities that competitors can offer. Similarly, according to the sexual selection hypothesis, infanticide is promoted as a consequence of females entering into an anestrus phase shortly after birth, a phenomenon known as lactational amenorrhea (van Schaik and Janson 2000). Hence, by spending more time unreceptive, females restrict the mating opportunities of males, who proceed to eliminate infants as a tactic for returning females to sexual availability. Perpetrators not only have a higher likelihood of copulating with targeted females, but also conceive their offspring. Thus, overall, infant killing in primates appears to be a consequence of both intersexual conflict and intrasexual competition, and appears to serve various adaptive functions.

Social structure and social dynamics also affect the probability of infant killings in predictable ways which suggest evolutionary design. For example, primate species living in one-male units are considered to be especially at risk of occurrences of infanticide compared to other species. Males from such units sire most of the offspring in the group. Therefore, when a dispersing male migrates and takes over, most of the young will be related to the former male. Infanticide allows the new male to obtain a reproductive monopoly and is commonly observed. Infanticide also occurs in primate species living in multimale groups (e.g., chacma baboons, *Papio ursinus*; and olive baboons, *P. anubis*). In contrast to one-male unit species, the average tenure of males living in multimale groups is brief. Thus, due to the risk of being deposed before siring any offspring, males may kill the infants of other males, which has the potential to increase their reproductive output (Beehner et al. 2005).

Paternity uncertainty is expected to be a protective factor against infanticide, as killing an infant when it is possibly one's progeny could have intense fitness costs. An interesting and complex phenomenon is observed with respect to this in primates: Females from species that carry and take care of their offspring on their own are more likely to have their offspring killed compared to

species that rely on the assistance of allocarers (i.e., individuals who engage in communal caring; van Schaik and Kappeler 1997). By having the support of kin or other helpers (e.g., males in marmosets and tamarins), communal females have a shorter interbirth interval, and even display sexual receptivity and proceptivity during pregnancy and shortly after birth. Even though males that copulated during nonconceptive periods do not sire more offspring compared to those that mate during ovulation, the confusion of paternity forces males to inhibit infanticidal tendencies to avoid killing their own offspring. The evolutionary context for females taking care of their young by themselves is considerably different. Due to the high physiological demands of investing in multiple infants at the same time, females limit the opportunities of conception by being unreceptive and in anestrus during periods of gestation and lactation and by increasing the temporal gap between births. However, at the same time, these modifications restrict the mating access of males, promoting the adaptiveness of infant killings by them. Higher infanticide rates are in fact observed in these cases.

An important realization is that evidences for an arms race between the sexes in terms of behavioral strategies to implement against infanticide would suggest that there are in fact evolutionary forces leading to adaptations involving infanticide. In fact, due to the high costs of infanticide, evidence suggests that females have evolved multiple counterstrategies to decrease the risks of losing younglings to attacking males. Depending on the social structure of each species, females can either concentrate or confuse male paternity. Thus, offspring of females who cohabitate or consort with a single male (e.g., OMUs species), receive the protection of the male, due to the copulation exclusivity increasing paternity certainty. Alternatively, paternity confusion occurs in societies with multiple males. In these conditions, concentrating paternity in a single male may not be sufficient to dissuade other males from attacking. Since takeovers in multimale groups are considerably common in multimale species, by copulating with numerous mates, females obscure the paternity of males, forcing attackers to refrain from killing the infant due to the risk of

eliminating their own young. Furthermore, females can advertise their receptivity to males through visual and vocal displays, or through sexual swellings peaking at times of ovulation. Other strategies employed by females to reduce the likelihood of infanticide by males include establishing friendship with a protector; dispersing with a deposed male; forming a coalition with other females or with kin; maternal vigilance and aggression; accelerating the weaning period; abandoning the infant, fetus reabsorption, or induced abortion.

Conclusion

Intragroup killings are observed across nonhuman species. Most of the victims are infants, whereas attackers are frequently adult males. Adaptive benefits obtained by infanticidal males appear to include returning noncycling females to estrus, eliminating future contenders and removing their genetic presence, decreasing the levels of current competition, and gaining access to resources. Support for these hypotheses has been found in various lines of research in different species, with research effort focusing especially in anthropoids. Attacks among adults have also been observed. However, differently from infanticide, victims and attackers in lethal conflicts among adults are mostly males. Gaining access to mates, eliminating rivals, and ascending in the hierarchy are some of the benefits obtained by successful attackers.

Nonhuman Reactions to Death

Noemie Bonnin and Alex K. Piel
Liverpool John Moores University, Liverpool,

Synonyms

Grief; Ritual; Thanatology

Definition

Death – The action or fact of dying or being killed; the point at which the processes that maintain an

organism alive no longer function. Dead – Deprived of life; opposed to alive and living; reduced to that state of a being in which the organs of motion and life have irrevocably ceased to perform their functions.

Introduction

Awareness of mortality is a human universal, evidenced by the pervasiveness of mortuary behavior and funerary rituals across human cultures, dating to Neanderthals over 40 ka. Humans exhibit diverse cultural variation in mortuary practices, in which treatment of dead bodies ranges from their consumption to the placement of them as far above or below ground as possible (Andrews et al. 2006). Moreover, compassionate behavior toward dying individuals is often regarded as a uniquely human trait, though recent reports of reactions to death and dying in nonhuman animals highlight the value of adopting a comparative evolutionary approach toward these behaviors. Here the diversity of nonhuman animal responses to death is reviewed and explanations for why animals differ so widely in their behavior toward dead conspecifics suggested.

Diversity of Responses to Death

Behavioral Adjustment to a Risk Exposure

If animal responses to carcasses are adaptive, individuals would be expected to view the bodies of dead conspecifics as disease-carrying agents and avoid or isolate them accordingly. Ants and aphids do exactly this, carrying carcasses to refuse piles, while honey bees remove dead brood members from their hives. Rats bury decomposing den mates. Nonetheless, there is information to be gleaned from dead or dying conspecifics, especially in assessing potential risk in an area. In some birds, seeing a dead conspecific induces alarm calling and subsequent risk-reducing behavior (Swift and Marzluff 2015), while in many aquatic organisms (Phylum Protista, Rotifera, Mollusca, Arthropoda, and Chordata), chemical cues perceived from injured, dead, or

digested conspecifics results in complete aversion to the local area.

Intense Interest in Conspecific Carcasses

Alternatively, some animals show intense interest in conspecific carcasses. In perhaps the best known example, African elephants spend unusually long periods at the sites where former herd members' bodies lie decomposing or even where only bones remain. They may also exhibit intense agitation and investigation (Merte et al. 2008). Less known, although behaviorally similar, American bison chase wolves away, before sniffing and nuzzling a calf's rotting body from their herd (King 2013). A similar reaction was reported by Strauss and Muller (2012) in wild giraffes, where following the death of a calf, giraffe mothers, and other herd members exhibited prolonged interest, including extensive vigilance, nuzzling, sniffing, and inspection of the carcass over several days. Intense interest in conspecific carcasses was also observed for a variety of cetaceans (i.e., rough-toothed dolphins, bottle nosed dolphins, Orca). The described behaviors include staying beside injured, dying, or net-trapped conspecifics and supporting sick or dead animals (infant as well as adult) at the surface (Ritter 2007).

Infant Corpse Carrying

Evolutionary biology predicts the extensive interest mothers' exhibit in dead offspring. Mammals that experience long gestation and development will benefit with the successful survival (and subsequent reproduction) of their offspring, thus premature abandonment of a suffering, but viable offspring carries high fitness costs. Examples of responses to dead infants date from almost a half-century ago and seem concentrated in the Order Primates. In numerous species, mothers and other group members carry dead infants from a few days up to several months after their death. Recently, Li et al. (2012) described three cases of mother responses toward dead infants in Yunnan snub-nosed monkeys. They showed that the age at which the infant died influenced the mother's behavior, whereby, for example, there was no carrying of stillborns versus extensive

carrying of dead infants who had survived to at least 1 month. Given that nonhuman primate females are hormonally predisposed to mothering in the last weeks of pregnancy, it is likely that hormones associated with parturition and lactation combined with the formation of a strong mother-infant attachment offer the strongest explanation for these behaviors. Between adults, the pre-dead relationship between the dead and the survivor seems to play an important role. Individuals that are more closely affiliated with the dead exhibit stronger reactions, either immediately or through longer-term behavioral changes. Given the importance of relationships to social animals, from alliance formation in dominance takeovers to cooperative foraging strategies, the loss of an ally can generate tremendous survival cost.

Sexual Arousal and Aggressive Interactions

If removing or isolating a carcass from one's home base makes adaptive sense by reducing potential exposure to disease, spending significant time investigating dead bodies seems maladaptive. However, sociosexual interactions with carcasses appear in several species (Piel and Stewart 2016). In marine mammals, Dudzinski and colleagues (2003) reported six to eight male dolphins spending almost three hours with a female carcass, focusing almost all their attention on its genital area, and simultaneously mate guarding the carcass while aroused. Similarly, mallards were observed to display homosexual and necrophilic behavior toward dead conspecifics, and in one anecdotal observation, a male squirrel was seen to approach and lay down in a copulatory posture next to a dead female. Stewart et al. (2012) detailed the responses of 16 (different) chimpanzees to the recently dead body of an adult female community member in Tanzania. Responses ranged from curious observation and passive investigation (e.g., smelling and grooming) to the shaking, dragging, and frustrated beating of the body. Similar responses were described in a nearby community, where adult male chimpanzees use the bodies of dead members in charging displays. Combined, these behaviors reveal a suite of responses, but they share individuals having

increased arousal levels, and possible confusion at the lack of response and overall state of the dead individual.

Human-Like Grieving in Captive Animals

One of the human universals in responses to death includes people grieving the loss of group members. This is a response to the permanent absence of the individual (e.g., death) versus the examples above, which describe responses to a dead body. Grief can be defined as changes in the survivor's patterns of social behavior, eating, sleeping, and/or of expression of affect (King 2013). While it is both difficult to define and rare to observe, there are documented cases of humanlike "grieving" among nonhuman animals. In captive pottos (*Perodicticus potto*), two individuals who survived a dead cage mate reduced their food intake after the death (and removal) of the conspecific. Captivity, however, allows surviving individuals to adjust their behavior at no cost to their survival. In the wild, natural selection may work against the visible expression of grief, since changes to routine and behavior may make an individual more vulnerable to predation or other lethal aggression from group members.

In perhaps the best description of a sequence of behaviors that approached human grieving, Anderson et al. (2011) reported on the death of an adult chimpanzee at Blair Drummond Safari Park, Scotland. Unique to this report were the detailed video records made before, during, and after the death. The authors described behaviors analogous to those that humans exhibit: chimpanzees appeared to care for the individual before death, to test for signs of life at the point of death, and to show signs of frustration after death, as well as subsequently to avoid the place where the death occurred (after the body was removed). The contrast in behavior pre-, during, and post-death seen in Anderson et al.'s study encouraged the authors to draw conclusions about the possible mental and emotional state of the surviving chimpanzees, specifically whether empathy and self-awareness – traits shared by humans and chimpanzees – allow us also to share with them an awareness of mortality.

What hampers our attempt to understand a nonhuman concept of death is similar to challenges facing any study of nonhuman cognition: How to know what others, unlike ourselves, know? Despite similar neuroanatomy, for example, humans and other primates exhibit vastly different capacities. Thus, it is both anthropocentric and biologically unfounded to expect nonhumans to express rituals as humans do, to communicate and express emotion as humans do. Thus, what can be expected? Besides against that of humans, against what baseline can others' responses to dead group members be compared? Until objective criteria are provided, analysis is limited by a species-specific lens, preventing much beyond a speculative interpretation of responses to death in heterospecifics.

Conclusion

The question of which species conceptualize death and how that is reified has implications for the evolution of human cognition and ritual. Fear of death has been argued to be a human universal. Full self-awareness and a theory of mind were likely propagated by positive natural selection and in some way must have benefitted ancestral hominins, opening the path for a distinction of "death" from "the dead." Others have argued to the contrary that these same traits may actually be evolutionarily detrimental to an individual or species. They would be a dead-end evolutionary barrier and would inhibit positively selected behaviors with large payoffs, like risk. Accordingly, a hominoid conception of death might have been blocked at some point during Great Ape evolution, helping to explain how animals can engage in fatal intergroup encounters, for example. Why then do some animals act as if they understand death? Elephants and other large herbivores investigate the bones of dead conspecifics; primate mothers carry dead infants for weeks or months; and, at least in captivity, animal responses to the dead resemble human grief with remarkable similarity.

If corpse removal from a fixed home base by colony-dwelling insects can be explained as an innate, evolutionary behavior, intense interest in

conspecific bodies may invoke more complex behaviors not as well known to scientists. Behavior associated with extensive vigilance, or high sexual or aggressive arousal, is presumably exhibited in an effort to gather more information about the unusual unresponsiveness of a carcass and demand more complex cognition, although not necessarily a conception of death. Elephant, giraffe, dolphin, and primates share large complex brains and fluid, complex social organizations that are cognitively demanding. It could be that the same faculties demanded to be a member of these groups are similarly useful in creating an awareness of one's position in the group and, in turn, the loss of others.

It is impossible to determine whether any of the animals described above have evolved or, more interestingly, developed an awareness or concept of death; only with concrete attempts to define expectations, look for patterns across anecdotes, and, eventually, test hypotheses can this topic be approached as a scientific question, grappling with the age-old question of human uniqueness.

Nonhuman Reciprocal Altruism

Definition

An evolutionarily stable strategy of enforcing cooperation by conditionally helping based on past experience of the recipient's help.

Introduction

How does the ruthlessly competitive process of natural selection lead to unselfish traits, such as a

tendency to help others? Many birds and mammals give alarm calls that help others escape predators, rather than simply and selfishly running away to get farther from the predator than other group members. Primates spend time and energy grooming the fur of others in their group. Vampire bats regurgitate a portion of their food to feed hungry groupmates, even nonrelatives, which failed to feed. If these costly investments in helping others could have been spent furthering one's own reproductive success, then why would natural selection reward these behaviors? The puzzle is that cooperative individuals pay a cost to increase the reproductive success of others, while more selfish individuals are not paying those same costs. All else being equal, selfishness should outbreed cooperation.

Evolutionary explanations of cooperation solve this puzzle. For example, natural selection rewards altruism when it is targeted to close kin. This is because close kin are more likely to carry the same genes underlying the altruistic trait, so genes linked to altruistic traits favor replication of those same genes in other individuals, a process called kin selection.

Robert Trivers (1971) proposed "reciprocal altruism" as an explanation for apparent altruism between nonkin. Reciprocal altruism theory views acts of helping as cooperative investments that yield a reciprocal cooperative return, and it makes the prediction that individuals will preferentially help those individuals who are likely to later help them, even if those individuals are unrelated. Many evolutionary biologists prefer the term "reciprocity" because "reciprocal altruism" is not truly "altruistic." In the standard terminology of evolutionary biology, altruism is helping behavior that decreases the actor's lifetime reproductive success. Reciprocity, by contrast, provides a long-term mutual benefit to both actor and receiver.

What is Reciprocity?

Here's how reciprocity works: Individual A makes a cooperative investment in individual B, such as social grooming, food

sharing, or risking one's safety to help an individual in need. This investment increases the probability that individual B will later make a reciprocal investment in A. The term "investment" implies that it is in some way contingent on the returns. So if A stops helping B, then B will eventually stop helping A, and vice versa. This contingency prevents free-riding, or cheating, because B cannot continually receive help from A without reciprocating. Reciprocity requires repeated interactions and contingent helping based on past experience (Axelrod and Hamilton 1981).

Some authors contrast "direct reciprocity" where A helps B because B helps A with "indirect reciprocity" where A helps B because B helps C. In this case, A evaluates B as a potential cooperator, and B helps C to build a reputation as a good cooperator. There is also the concept of "generalized reciprocity" where A helps B because A was helped by any other individual. The tendency of humans to both cooperate and punish noncooperators, even in one-shot economic games without repeated interactions, has been called "strong reciprocity," but this behavior is most likely a by-product of natural selection shaping human decision-making in such a way that humans treat most or all social interactions as if they might be repeated (Delton et al. 2011).

What is the Evidence for Nonhuman Reciprocity?

There are many natural examples of organisms in nature making cooperative investments that are contingent on the cooperative returns. Unless otherwise noted, the older examples below are taken from a review by Carter (2014) and the references cited therein, while more recent studies (post-2013) are cited here. In the cleaner-client fish mutualism, small cleaners eat dead skin off larger "client" fish, which benefits both parties. But the cleaners can also "cheat" by eating mucus or live tissue, which benefits the cleaner but hurts the client. Both cleaners and clients enforce cooperation through reward and punishment (direct reciprocity) and through image scoring (indirect reciprocity). Clients abandon or chase cleaners

that cheat, and they avoid cleaners that they observe cheating with other clients. Cleaners behave more cooperatively when they are punished and when they are observed by other clients. Cleaners also enforce good behavior in other cleaners; they will punish cheating cleaners that might otherwise drive good clients away, an example of third-party punishment.

Even brainless organisms can perform a simple version of reciprocity. Plants contingently trade resources with symbiotic partners such as fungi and bacteria. By diverting resources to different structures, plants can selectively eliminate symbionts that do not provide good returns. For example, plants provide mycorrhizal fungi with carbon in exchange for phosphorus. Both parties reward high returns and punish low returns, by delivering more or less of the resource to match the amount of the return.

Some authors consider individual recognition and memory to be a prerequisite for reciprocity, in addition to contingency and repeated interactions. In one set of experiments, rats were trained to pull a lever to deliver food to conspecifics, and the experimenters then showed that the rats were more likely to deliver food to partners that previously delivered food to them. Anonymous help increased pulling by 20 %, which shows “generalized reciprocity,” and help from the same partner increased it an additional 51 %, which shows “direct reciprocity” based on recognition and memory of specific individual’s past behavior.

In nature, contingency in helping is most detectable in scenarios where animals cannot choose their partners. One example involves songbirds on neighboring territories. As male songbirds on neighboring territories become familiar with each other, they tend to reduce aggression towards one another as compared to strangers, which is called “the Dear Enemy effect.” By experimentally simulating territorial intrusions by neighboring males, experimenters found that male song sparrows increase their aggression to previously intruding neighbors but not to those that did not. Either reducing or escalating aggression is based on what the neighboring rival did previously.

Reciprocity might also occur between songbird parents raising offspring together. Great Tit parents were found to feed nestlings in a balanced alternating pattern unexplainable by foraging or begging times. Each parent increased feeding rates after their partners contributed but reduced their feeding rate by about 25 % until their partner contributed (Johnstone et al. 2014). These two examples from songbirds, rival males and allied parents, show that reciprocity results from the mix of cooperation and conflict that occurs in all social interactions that evolve via natural selection.

Some of the best experimental evidence of reciprocity comes from mobbing behavior of birds. Experimenters used fake owls to induce cooperative mobbing in 44 triads of pied flycatcher mated pairs, with each triad consisting of three equidistant nestboxes. One pair (the victims) was exposed to a fake owl near their nestbox to induce mobbing, another pair (the defectors) was prevented from mobbing, and the third pair (the helpers) was left untreated. Therefore, the “helpers” always helped the “victims” with mobbing, but the “defectors” never did. Later, when the authors simultaneously presented the previous “helpers” and “defectors” with owls, the previous “victims” helped the previous helpers in 30 of 32 trials. In a follow-up experiment, when the previous “defectors” were presented with an owl, the “helpers” (but typically not the “victims”) joined the “defectors” in mobbing, as expected if only the “victims” experienced a defection. Later experiments further ruled out the possibility that reciprocal mobbing at nestboxes was purely a by-product benefit of selfish behavior. Astonishingly, the degree of reciprocity was also sensitive to whether the failure of partners to mob was caused by their complete absence. When experimenters used playbacks of recordings to make pairs seem present but unwilling to join, the rate of defection increased dramatically.

Much like mobbing birds, pairs of fish will also sometimes cooperatively approach and inspect predators, such as larger predatory fish. They appear to do this to assess the situation while maintaining the safety of a companion. One hypothesis is that the fish enforce partner cooperation by approaching closer only if their partner

swims beside them. This hypothesis is supported by several experimental results. There are differences in predator inspection behavior of fish from populations with either high or low predation. Predator approach behavior is riskier for single fish and leading fish. Predator inspection involves partner recognition, it is contingent on a partner's past and present predator inspection behavior, and it is more likely to occur with partners that have a history of social interaction.

As in several of the examples above, reciprocity often involves clear turn-taking. Other examples include two hermaphroditic fish that take turns trading egg or sperm and when migrating birds take turns flying in the more costly lead position of a flight formation (Voelkl et al. 2015). But strict turn-taking is not a prerequisite for cooperation, and it does not occur in many long-term reciprocal relationships that may involve the exchange of different kinds of help. For example, primates create and maintain enduring social bonds that involve multiple forms of cooperative investments. Chimpanzees of both sexes appear to exchange several different commodities, including grooming, sex, support, and food, resulting in balanced relationships over extended periods. Similar to humans, nonhuman primates cooperate in a more strictly contingent manner with partners that are actually *less* bonded. Most experimental evidence for strict short-term contingency therefore comes from more simple systems such as those with rats, plants, and fish described, because it is difficult to alter a complex friendship-like social bond in a short window of time.

Many cooperative social bonds form between relatives, which can make reciprocity difficult to distinguish from nepotism. Moreover, reciprocity and nepotism can occur simultaneously because reciprocity can enforce cooperation between relatives. The best evidence for this comes from vampire bats (see ► [“Blood Sharing by Vampire Bats,”](#) this volume).

Many authors view reciprocity as a controversial explanation for cooperation, but this debate is mostly or entirely semantic: it revolves around different definitions of reciprocity that are narrow versus broad or functional versus mechanistic. For

instance, some authors use “reciprocity” for a calculated investment where individuals suppress selfishness to intentionally and strategically help another with the expected outcome of receiving a given amount in return, which requires the ability to plan ahead, value future over present outcomes, and maybe even count. This very narrowly defined kind of reciprocity is the basis for human trade, but it all but excludes its importance in anything but humans. It also departs from the original broader definition, proposed by Trivers (1971) and Axelrod and Hamilton (1981).

One criticism of reciprocity theory is that it historically focused on dyads in isolation and thus ignored the vast importance of partner switching and choice. Why reward and punish a single partner, when one can simply switch to a different partner? Biological market theory (Noë and Hammerstein 1994) addresses this gap by starting with the assumption that cooperative investments lead to cooperative returns and then producing testable predictions for how market effects, such as the supply and demand of available partners, will influence both partner choice and partner control (reward and punishment). When one partner holds more bargaining power, trade can be asymmetric. For example, when experimenters created a situation when only one low-ranking monkey could open a food box, she subsequently received far more grooming. But when a second monkey was given this food-provisioning power, the grooming she received went up, while the grooming the first provider received decreased. The monkeys make cooperative investments based not only on past returns but also the relative value of alternative investments.

Conclusion

Reciprocity is a controversial but important explanation for cooperation.

Definition

Nonhuman sexual conflict refers to any type of conflict that arises between members of the animal kingdom as the result of male and female reproductive interests being at odds with one another.

Introduction

In much of the animal kingdom, mating is not a cooperative process. Instead, it is marked by conflict and arms races between males and females to achieve their opposing reproductive goals (Parker 1979). Such conflict can be manifested in many forms, but they fall into two broad categories: precopulatory conflict and postcopulatory conflict (Parker 2006). The following sections provide brief overviews of the most commonly studied forms of conflict in nonhuman species under these two categories.

Precopulatory Conflict

In general, precopulatory conflict is centered around identification of potential mates before any DNA has been exchanged (Parker 2006). Typically, such conflict arises from discrepancies in mate value between partners. For the majority of species, there are differences in choosiness between males and females when selecting an appropriate mate. This is mainly due to the fact that eggs tend to be larger, more complex gametes than sperm which makes them more energetically costly to produce (Bateman 1948). Additionally, females of most (but not all) species have a larger minimal parental investment in offspring in forms that include gestation, lactation, and incubation (Trivers 1972). Under such circumstances, females typically have lower reproductive potential than males because they are restrained by a limited number of eggs and heavy parental investment. Therefore, they tend to be choosier when seeking a mate as a poor mate choice can be more likely to lead to reproductive failure relative to males (Parker 1979). Males, on the

other hand, benefit the most from a reproductive strategy that involves indiscriminate mate choice in an attempt to produce as many offspring as possible (Trivers 1972).

This asymmetry in choosiness between the sexes has been observed in a variety of species. In some deer species, for example, a routine mating practice is lekking, which refers to males displaying themselves in groups to females and then the females inspecting them and choosing the male of best quality as a mate (Massei and Bowyer 1999). Does prefer bucks with the largest antlers, as this trait is not only indicative of success in aggressive encounters with other males, but it also is an indicator of good genes. Specifically, a study on white-tailed deer found that bucks with the biggest antlers also had better immune function and greater resistance to parasites (Ditchkoff et al. 2001). Choosing bucks with this characteristic will lead to those better genes being passed on to the female's offspring.

Another consequence of greater female choosiness is greater variance in reproductive success between the sexes (Bateman 1948). Because females only choose the highest quality males as mates, there should be at least some males that are not deemed high enough in quality as mates and therefore do not reproduce at all. Hence, males tend to have greater variance in reproductive success than females. However, one reaction to both the higher male propensity to fail to find a mate and the high degree of selectivity in females for males is to engage in sexual coercion. Although this is a known reason for sexual coercion, it is also practiced by reproductively successful males in an attempt to further increase their reproductive success. Such a strategy is favorable to male reproductive interests at the expense of the female's ability to choose the best quality mate (Clutton-Brock and Parker 1995).

This form of sexual conflict is common in nonhuman species, and it is studied more heavily in some than others. For example, in many species of waterfowl, such as ducks, males engage in forced copulations with females that are typically already mated to a regular partner (McKinney and Evarts 1998). Additionally, many of the males engaging in sexual coercion have a regular partner

as well. Male ducks tend to force copulation upon females that are not currently accompanied by their regular male partner, as male partners tend to be able to successfully defend against intruding males. However, in cases where a female is left alone and is forced into copulation by a strange male, if her regular partner arrives during the act of sexual coercion, he will fight off the intruder but will also force his mate to copulate with him immediately after to increase paternity certainty (McKinney and Evarts 1998).

Sexual coercion among ducks has been such a common part of the species' ancestral history that female genitalia has evolved to decrease the chances of successful forced copulation and therefore give the female an advantage in sexual conflict. According to Brennan et al. (2009), the duck penis has a corkscrew shape that spirals in a counterclockwise direction, while the female oviduct spirals in a clockwise direction. This morphology makes it difficult for males to penetrate the oviduct and therefore achieve fertilization during forced copulation.

Precopulatory conflict can also occur among hermaphroditic species. In this case, conflict is usually focused on which member of the mating pair will take on the male and female role in terms of parental investment. Usually, both members prefer the male role as this allows for the highest reproductive potential along with the lowest amount of parental investment (Michiels 1998). Therefore, hermaphroditic species have developed antagonistic ways to approach copulation to compete for the opportunity of paternity. In one such species, flatworms, a mating pair will struggle with one another in an attempt to be the first to inseminate via a stabbing motion with its penis. The individual who stabs first tends to father more offspring in more individuals, therefore increasing reproductive success over other individuals that are not as successful in the stabbing battles (Michiels and Newman 1998).

Postcopulatory Conflict

In cases where females may not be able to choose their reproductive partners as a consequence of

forceful insemination, there are still ways in which they can prevail in sexual conflict. The activities leading up to and including intercourse are only part of the story, as arms races between males and females are just as prevalent after the completion of copulation. Sexual conflict at this point in time usually revolves around which male will achieve paternity.

Sperm competition refers to a situation in which sperm from at least two different males are present in a female's reproductive tract simultaneously and thus compete with one another for the opportunity to fertilize ova. Sperm competition could arise as a consequence of sexual coercion such as in the case of ducks as described earlier. However, in many nonhuman species, females actively promote sperm competition by mating with multiple males during a brief period (such as a mating season) (Parker 1970). It has been suggested that such a strategy still allows for female choice, in that only the most adept sperm (and presumably that also translates to the male with the best genes) are successful in such competition.

For instance, chimpanzees engage in promiscuous mating such that most members of a community mate with multiple members of the opposite sex. Under these circumstances, there is a high risk of sperm competition (Harcourt et al. 1981, 1995). Even though, in terms of precopulatory sexual conflict, the most socially dominant ranking males secure the highest degree of sexual access to females, their rates of paternity do not match their copulation frequency. The males with the highest rates of paternity are those that are somewhat younger than the most dominant males, and this is likely due to the superior quality of sperm from younger males (Wroblewski et al. 2009). Sperm production is vulnerable to senescence, and in older primate males declines in semen volume, count, motility, and morphology are commonly found (Kidd et al. 2001). Therefore, it is likely that female chimpanzees are optimizing their chances of reproductive success in sexual conflict in precopulatory contexts by allowing copulations with high-ranking males and in postcopulatory contexts by allowing copulations

with younger males. Use of both strategies allows ultimately for the best genes to be passed to the next generation.

Not only does the quality of sperm itself help with the outcome of sperm competition, but also penile ornaments play a role. In many species, especially various insects, the penis has spines or some other form of weaponry that actually cause physical damage to the female during copulation. This has developed to discourage the female from seeking additional males and thus produces an advantage in intersexual conflict (Eberhard 1985). In addition to spermatozoa, other chemical components in seminal fluids contribute to sexual conflict. Specifically, substances in seminal fluids have been known to decrease the female's desire to mate with another male and/or mimic her own body's hormones to trigger oviposition as has been observed in grasshoppers, katydids, and fruit flies (Eberhard and Cordero 1995).

Even after accounting for sperm competition, there are still ways to manipulate the outcome of sexual conflict. Female animals sometimes induce abortions in the event that the expected offspring would have poor survival prospects. Mice are known to selectively abort their pregnancies (known as the Bruce effect) when their mate is replaced by a novel male, as unfamiliar males typically commit infanticide when exposed to unrelated offspring (Gangrade and Dominic 1984). Such a strategy saves the female from wasted effort in offspring that are unlikely to survive and prepares them for estrus so they can bear the offspring of the new male. The Bruce effect has even been observed from exposure to just the scent of urine from an unfamiliar male (Gangrade and Dominic 1984). Alternatively, some species use infanticide as a method of inducing estrus rather than spontaneous abortion. For example, when a new male lion takes over a harem of lionesses, he systematically kills all the lion cubs in the harem so as not to invest in unrelated offspring; this also induces estrus in the female lions so that the new male can increase his own reproductive success despite the females' wasted parental effort (Pusey and Packer 1994).

Conclusion

This was just a brief summary of the types of sexual conflict that occur in nonhuman species, and some form of sexual conflict has been observed in virtually all species that have been studied. This type of conflict exists at the precopulatory level in the form of mate value discrepancy or sexual coercion, or at the postcopulatory level in the form of cryptic female choice and sperm competition. For both males and females, they have evolved adaptations to skew the outcome of this conflict in their favor at the expense of their partner. In many nonhuman species, the individuals with the most reproductive success are the ones that are best able to manipulate their partner.

Nonhuman Tool Use

Ivo Jacobs and Mathias Osvath
Lund University, Lund, Sweden

Synonyms

Instrumentation; Tool behavior; Use of implements; Use of instruments

Definition

The external employment of an unattached or manipulable attached environmental object to alter more efficiently the form, position, or condition of another object, another organism, or the user itself, when the user holds and directly manipulates the tool during or prior to use and is responsible for the proper and effective orientation of the tool. (Shumaker et al. 2011, p. 5)

Introduction

Nonhuman tool use has long been a source of much fascination. Claims of human uniqueness have often revolved around the ability to use and manufacture tools. When Jane Goodall discovered the extent of tool use by wild chimpanzees in the 1960s, Louis Leakey commented that “now we must redefine tool, redefine man, or accept chimpanzees as humans” (Goodall 1998, p. 2184). After countless observations of animals using and manufacturing tools, it is now evident that “man the tool-maker” (Oakley 1956) is an erroneous definition of our own species.

Tool use in primates has been known for a long time. Wild chimpanzees and capuchin monkeys were observed by explorers in the sixteenth and seventeenth century to throw stones at intruders and use stones as hammers to crack hard nuts. Alfred Russell Wallace, who independently of Darwin formulated evolution through natural selection, described how three wild orangutans dropped branches toward him as he tried to shoot them (Shumaker et al. 2011). It was often

assumed that tool-use behavior was learned from humans. The variety of tool use in captive chimpanzees had been described before Goodall – notably Köhler’s (1927) experiments on Tenerife between 1913 and 1920 – but her discovery of habitual tool use in wild populations showed this behavior to be independent of human influence (Shumaker et al. 2011).

“Necessity is the mother of invention” is the moral of Aesop’s fable on the crow and the pitcher. It involves a thirsty crow trying to drink from a pitcher, but the water level is too low. He collects stones and drops them into the pitcher until the water reaches the top. Recent research has shown this to be more than a fairytale. Some crow species and their relatives – forming the corvid family including ravens, crows, magpies, and jays – have successfully dropped stones into a water-filled tube to obtain floating food (see Fig. 1). Similarly, some apes spit water into a tube containing a peanut to bring it within reach (Jelbert et al. 2015).

In his final book, Charles Darwin studied the intelligence of earthworms. He noticed how they often used leaves to plug the entrance to their burrows. Such behavior is today defined as tool use. Darwin formulated several functions of this behavior, such as predator protection, insulation, or keeping the burrow free from dirt and water.

Nonhuman Tool Use, Fig. 1 A New Caledonian crow drops stones into a water-filled tube, rather than a sand-filled tube, to obtain a floating reward. Reproduced from Jelbert, S. A., Taylor, A. H., & Gray, R. D. (2015). Investigating animal cognition with the Aesop's Fable paradigm: current understanding and future directions. *Communicative & Integrative Biology*, 8, e1035846. doi: 10.1080/19420889.2015.1035846. <http://www.tandfonline.com/doi/abs/10.1080/19420889.2015.1035846> CC BY-NC 3.0: <https://creativecommons.org/licenses/by-nc/3.0>

The earthworms handled leaves optimally by taking their differing shapes into account, and they incorporated objects never encountered before, such as pieces of paper or leaves of foreign plants (Crist 2002). Such discoveries have been important in lifting animal tool use to scientific level, wherein the study of animals ranging from earthworms to chimpanzees has become acceptable in wild and captive conditions, with questions on the types, function, ecology, evolution, and cognition of tool use.

Modes and Functions of Tool Use

Following Leakey's prediction, tools have been frequently redefined. Most contemporary definitions do not focus on human uniqueness or cognitive requirements and are instead descriptive in terms of actions and objects used. Critically, the user exerts some control over the tool through direct physical manipulation. If all types of interaction with external objects for various purposes are considered tool use, then it would become overly broad, including behaviors such as climbing a tree. After decades of discussion, the definition of Shumaker and colleagues (2011) in their book *Animal Tool Behavior* appears to have the fewest problems and is therefore used here.

They describe 22 modes of tool use, which are operationally descriptive as motor actions and are independent of possible functions. They nonetheless emphasize that tool use, unlike object manipulation and object play, requires purposive behavior. Purposiveness is reflected in the definition of tool use as "to alter more efficiently the form, position, or condition of another object, another organism, or the user itself" (Shumaker et al. 2011). Consequently, an ape passively dislodging branches while fleeing through the canopy does not constitute tool use, but one aiming and dropping branches to discourage gun-wielding naturalists is. That exemplifies the tool-use mode *drop*.

All modes can be assigned one or several of seven functions. For instance, an ape might drop a branch to (1) amplify mechanical force, which can cause more damage to the intruder; (2) extend its

reach, which enables it to inflict damage to the intruder without having to come closer; and (3) create or augment signal value of social display, which could be the case when it intends to intimidate rather than harm the intruder. This example illustrates that although all tool use is purposive, the exact function does not necessarily follow from the assignment to a certain mode. All tool-use modes and functions described by Shumaker and colleagues (2011) are presented in Table 1.

The list of tool-use modes and functions is not exhaustive. Shumaker and colleagues formulated these categories after they catalogued animal tool behavior. Additional observations may thus not fit into these categories. For example, New Caledonian crows are habitual tool users in several modes, and novel findings not only show their tool use to belong to more modes than initially described, but also that novel modes may have to be formulated. They have been observed to insert tools into objects to transport them, with one bird having trouble handling the large target object, which became transportable after inserting a stick into it (Jacobs et al. 2016). Novel modes can also be found in species never having been observed to use tools. Greater vasa parrots held dates and pebbles in their beak and used their tongue to grind them against seashells, which serve as important calcium sources. This appears to be the first report of this kind of tool use in animals (Lambert et al. 2015).

In contrast, Bentley-Condit and Smith (2010) classify tool use based on biological function. Their ten categories are food preparation, food extraction, food transportation, food capture, physical maintenance, mate attraction, nest construction, predator defense, agonism, and other. However, assigning a behavior to one of these categories is often problematic. For example, distinguishing defense and agonism can be difficult, and both categories are excessively broad. When reformulated into the modes from Table 1, defense and agonism can take forms such as drop, throw, slap, club, jab, stab, block, affix, apply, and drape. Furthermore, highly similar behaviors are not forced into different categories because they serve different functions. Bentley-Condit and

Nonhuman Tool Use, Table 1 Tool-use modes and functions described by Shumaker et al. (2011, p. 13–14). The precise definitions are excluded because the labels are sufficiently descriptive for present purposes

Mode	Function
Drop	Create or augment signal value of social display; amplify mechanical force; extend user's reach
Throw	Create or augment signal value of social display; amplify mechanical force; extend user's reach
Drag, roll, kick, slap, push over	Create or augment signal value of social display; amplify mechanical force
Brandish, wave, shake	Create or augment signal value of social display; camouflage; bodily comfort
Bait, entice	Extend user's reach; create or augment signal value of social display
Club, beat	Amplify mechanical force
Pound, hammer	Amplify mechanical force
Pry, apply leverage	Amplify mechanical force
Dig	Amplify mechanical force
Jab, stab, penetrate	Amplify mechanical force; extend user's reach
Reach	Extend user's reach
Insert and probe	Extend user's reach
Scratch, rub	Amplify mechanical force, bodily comfort
Cut	Amplify mechanical force
Block	Amplify mechanical force; extend user's reach
Prop and climb, balance and climb, bridge, reposition	Extend user's reach by expanding accessible three-dimensional space, bodily comfort
Hang	Extend user's reach by expanding accessible three-dimensional space
Contain	Effective control of fluids and small solid objects
Absorb	Effective control of fluids, bodily comfort
Wipe	Effective control of fluids and small solid objects, bodily comfort
Affix, apply, drape	Create or augment signal value of social display, camouflage, bodily comfort
Symbolize	Abstract or represent reality

Smith (2010) consider using a stick to obtain out-of-reach food as food capture, but would classify the exact same behavior as other tool use if the target were a nonfood object. We favor the approach of Shumaker and colleagues because its modes are descriptive with each having multiple possible functions that are independent of the tool actions themselves.

Ecology

Why do animals use tools in the first place? It was long believed that captive animals use tools because they have plenty of time to play with objects or because they copied humans. Some researchers have argued that tool use marks a qualitative difference between animals and

humans, in that we strongly depend on tools for our survival, whereas it is trivial for other animals. However, some species habitually use tools in the wild, which constitutes a significant aspect of their foraging ecology (Shumaker et al. 2011). Tool use takes time and effort, requires dexterity, involves learning, and exposes animals to predators. The habitual tool use of some species suggests that there must be benefits that outweigh these costs.

There are four non-mutually exclusive hypotheses about variation in tool-use frequency and diversity between natural populations (Fox et al. 1999; Rutz and St Clair 2012; Sanz and Morgan 2013). The *necessity hypothesis* follows the proverb that necessity is the mother of invention in suggesting that tool use is an emerging strategy to deal with resource scarcity. For instance, woodpecker finches use sticks and

cactus spines to extract embedded arthropods on the Galápagos Islands. They spend more time and obtain more prey using tools in arid areas compared to wet areas, which have a higher availability of other food sources and therefore also a higher population density. Although tool use is more time consuming than other foraging techniques, it is more profitable during the dry season in the arid zone because larger and more energy-rich prey can be captured (Tebich and Teschke 2013).

The second hypothesis is the *opportunity hypothesis*, which states that increased encounters with target items and tool materials lead to more frequent tool use. For example, orangutans appear to use tools more frequently with increased presence of social insects. Although orangutans are mostly arboreal and frugivorous, insectivory is more common in one Sumatran population because social insects cannot build nests on the swampy forest floor and instead inhabit tree holes. This exposes orangutans to a food source they would not otherwise often encounter, which consequently requires them to use extractive foraging tools, in modes such as penetrating, reaching, inserting, and probing. Without this foraging opportunity, tool use in orangutans in this area would be less frequent or diverse (Fox et al. 1999).

The third hypothesis is the *relative profitability hypothesis*, which proposes that tool use arises when it is energetically more profitable than alternative foraging techniques. Tool use plays an important role in the feeding ecology of New Caledonian crows which, like the woodpecker finches, inhabit islands without woodpeckers or similar competitors. They use three distinct tool types made from plant material. Non-hooked stick tools are made from sticks, grass, and leaf petioles and are often used to extract wood-boring beetle larvae from their tree burrows. Crows use such tools to poke larvae until they bite it, after which it can carefully be withdrawn. Hooked stick tools can be used to extract other kinds of prey and are unique in the animal kingdom. Pandanus tools are made from screw pine (*Pandanus*) leaves, which have barbed edges

that are employed during foraging. Although little is known about tool use by wild New Caledonian crows, it has been shown that these wood-boring larvae comprise a substantial intake of lipids and protein, which indicates the significance of using tools as these larvae would be unavailable otherwise. Other factors that may have enabled the development of habitual tool use are reduced risk of predation, absence of other extractive foragers, and seasonal prey scarcity. New Caledonian crows appear to have evolved several morphological adaptations to tool use, such as a relatively straight beak and a large binocular overlap, which shows its evolutionary significance (Rutz and St Clair 2012).

The final hypothesis is the *limited invention hypothesis*, which suggests that the invention of novel tool use is relatively rare, and its spread and maintenance depend on social learning from conspecifics. This hypothesis is an important explanation of tool use in chimpanzees, which are the most frequent and diverse (20 out of 22 modes) tool users among nonhuman animals in the wild (Shumaker et al. 2011). Nonetheless, there is an enormous variation in the tool repertoire of different populations, which are therefore often considered as different cultural variants. The use of termite-fishing tools by one chimpanzee population in the Republic of Congo is unrelated to temperature, rainfall, fruiting or flowering tree occurrence, or abundance of leaves. Other tool use types have ecological correlates: using tools to extract ants is more frequent with increasing rainfall, and tool use for gathering honey is higher in months with more flowering trees. The chimpanzees consumed more leaves during periods of fruit scarcity, but they did not increase their tool use – a finding that goes against the necessity hypothesis. For the most part, their tool use was not strongly predicted by opportunity either, due to it being mostly independent from ecological factors. The relative seasonal profitability of different foraging techniques may partially explain these results. Party size was relatively small during tool use bouts, and social tolerance may also have enabled less-skilled individuals to learn about the location of tool-use sites, the tools

required, and the techniques involved. Through social learning and conformity, tool-use innovations can spread throughout the population (Sanz and Morgan 2013).

Evolution

Tool use is clearly beneficial for some species, although it can vary strongly between populations and tool-use modes. However, for many species, tool use has only been described in a single subject or mode, in captivity only, or with little to none energetic or nutritional significance. Here follows a brief description of the taxonomic variety of animal tool use, based on Shumaker et al.'s (2011) catalog, which is the most extensive to date. Novel tool-using species and modes are frequently described, so this overview is by no means exhaustive, but aims to illustrate the diversity of tool modes and their occurrence in perhaps unexpected species.

Several invertebrate species use tools, as already described by Darwin in the case of earthworms. Ant-lion larvae dig pitfalls in the sand and wait at the bottom for prey to fall in. If prey attempts to escape, the larva throws sand toward it to bring it into reach. Some digger wasps create subterranean burrows in which they deposit eggs and prey for their larvae to feed on. They seal and conceal the burrow by holding an object in their mandible and then pound the entrance and the surrounding area. Several ant genera construct and repair their nests by moving around larvae that secrete sticky silk that cements parts of the nest together. Sea urchins have been observed to cover themselves with objects for camouflage, which reduces the chances of predation. Boxer crabs attach stinging anemones to their claws, which aids in defense, food capture, and self-maintenance. Nest-casting spiders hold a part of their web between their legs and throw it toward passing prey to capture it. Carrier shells are sea snails that fittingly to their name attach empty shells to their own, which may aid in protection and camouflage. Veined octopuses sometimes carry coconut halves that they use as a shelter when threatened.

Tool use in fish, amphibians, and non-avian reptiles is uncommon. The best-known case of tool use in fish is the archer fish, which shoots water jets at prey above water. They can shoot up to 3 m far, and experienced fish have a near-perfect accuracy at a distance of 1 m. When presented with food in a small pipe, stingrays remove it by using water as a tool by creating currents with their fins or by blowing water through the pipe. Horned frogs throw mud onto their backs with their feet to camouflage themselves. Recently, American alligators and mugger crocodiles were seen to place twigs on their snouts during the nesting season of local birds, which are greatly attracted to nest material during this seasonal shortage. The sticks function as bait that attracts these birds, which can then be caught by the waiting crocodilians (Dinets et al. 2015).

Reports of tool use in birds are more numerous. Egyptian vultures often drop and throw stones on ostrich eggs to crack them. They've also been observed to use stones to kill lizards. Like the crocodilians described above, many birds bait prey with enticing objects. For example, burrowing owls place dung near their burrows to attract dung beetles. Brown-headed nuthatches customarily hold bark scales in their beak to pry away tree bark and expose invertebrates. A Steller's jay and an American crow have once been seen to use a stick as a weapon to jab at each other. Many parrot species use a variety of objects to scratch themselves. A rook plugged water drains in its aviary to create a drinking and bathing pool during hot days. An American crow repositioned a perch to reach an inaccessible location. A gila woodpecker dipped bark into honey for absorption and then transported it to his fledglings. Hawaiian crows are extinct in the wild, but nearly all captive subjects use stick tools for extractive foraging (Rutz et al. 2016). Male satin bowerbirds build and paint bowers to attract females. They hold bark pieces in their beak and dip them into the "paint" (e.g., charcoal, grass, mud, fruit pulp), which they then apply to their bowers. The most widespread tool-use type in birds is anting, which involves applying certain invertebrates, plants, or objects to their plumage.

Many of these tools have acidic compounds that may aid feather maintenance or kill ectoparasites.

Non-primate mammals also use tools in various ways. Beavers managed to overflow their enclosure by blocking pipes with sticks, leaves, and mud. Wood mice place conspicuous objects throughout their home range that might function as orientation points. Polar bears sometimes carry or roll large objects that they throw at prey during hunting. Sea otters place stones on their abdomens and pound hard-shelled prey against them. Some use an additional stone as a hammer. They may also apply kelp to their bodies to increase their buoyancy. Captive giant pandas were seen to clean their undersides by rubbing them with soil held in their front paws. North American badgers capture ground squirrels by blocking the burrow entrances with soil and vegetation. Elephants use tools in various ways. They sometimes destroy electric fences by dropping logs or rocks on them. Throwing, kicking, or rolling objects at intruders and competitors is a common behavior. They often use tools for self-maintenance, such as using leafy branches as fly swatters or sticks to scratch their bodies in places their trunks can't reach. They have been known for a long time to place vegetation and soil over dead elephants and humans. Some bottlenose dolphins carry sponges on their rostra for protection while digging into the ocean floor searching for prey. Several whale species use bubbles to trap fish, but the exact mechanism is unclear.

Tool use in primates is the most studied and perhaps also the most intuitive due to its similarities to human tool use. Only a few cases of tool use in prosimians are known, the most typical being the application of urine or other scents to their bodies. Many New World monkeys drop or throw objects at competitors and intruders. Capuchin monkeys are the most renowned tool users of this group. They habitually pound stones against nuts, dig up roots with stones, use probing sticks in extractive foraging, and apply odorous objects to their fur. Two have even been observed to bait ducks with bread and then kill them. Throwing and dropping objects is also common in Old World monkeys. Some macaque populations frequently use stones to hammer on

hard mollusks or floss their teeth with hair. Many monkeys learn to use reaching tools in captivity. Most ape species use tools extensively in the wild and in captivity. Like in other primates, agonistic dropping and throwing is common. Only a few additional anecdotes of tool use in gibbons are described. The list of tool use modes in great apes is very extensive, but a general pattern is that chimpanzees and orangutans are more habitual and diverse (nearly all modes) tool users than gorillas and bonobos.

The archeological record reveals how tools have affected the evolution of the hominin lineage, with the oldest found tools dating back 3.3 million years. Considering the advanced spatial reasoning and dexterity required to manufacture and use these stone tools, they had likely been around for longer. It is therefore possible that the last common ancestor of hominins and chimpanzees used such tools. Primate archeology aims to uncover the origins and context of tool use through time. Chimpanzees and capuchin monkeys are particularly valuable species because they use stone hammer tools, which are preserved better than organic tools. Assemblages of stone tools used by chimpanzees date back at least 4,300 years, which corresponds with more than 200 generations (Haslam et al. 2009). Similar assemblages have been found in Brazil, where bearded capuchins have been using stone tools for at least 600 years, corresponding to approximately 100 generations (Haslam et al. 2016). The continued use of such tool sites highlights the importance of tool use for these two nonhuman primate species, with similar finding expected for others – possibly even non-primates. Because stone tool use is rare and capuchins are only distantly related to humans, it seems to have evolved independently in these lineages.

In contrast to longstanding opinions of only species closely related to humans using tools, Shumaker et al. (2011) did not find clear ecological or phylogenetic predictors. Hunt and colleagues (2013) recognize two types of tool users. Tool use in invertebrates and fish is mostly innate, stereotyped, asocial, ubiquitous within species, conserved throughout their phylogeny, and highly context-dependent (invariable inflexible). Tool

use in mammals and birds is, in contrast, less stereotyped, more flexible, innovative, requires higher cognitive abilities, relies more on learning (both individual and social), has distinct developmental phases, shows fewer phylogenetic patterns, and has a higher proportion of tool-using species. The only exception is anting in birds and agonistic throwing in primates because they are more widespread and stereotypical. Hunt and colleagues suggest that the rarity of animal tool use originates in a lack of suitable preexisting behaviors. Stereotypical tool use arises from certain object-related mechanical actions, an appropriate ecological context, and phenotypic change. For example, ant-lion larvae dig pits in the sand with stereotyped head movements. Directing this movement toward insects constitutes tool use because the sand serves as a throwing tool with the function of displacing prey. This change in context became adaptive and could be maintained and spread in a species by specifically directing this behavior toward certain stimuli leading to increased prey capture.

Hunt and colleagues (2013) also describe three constraints on flexible tool use: learning that an object can be used to solve an otherwise difficult problem, working memory capacity for dealing with increased sequential and relational complexity, and manipulation abilities necessary for executing the behavior. In a similar vein, Sanz and Morgan (2013, p. 12) claim that ecological opportunity is not sufficient to support widespread tool use and that “emergence of a particular tool behavior may require a certain threshold of abundance: (i) to provide repeated exposure to the target resource, (ii) to make the foraging for this food resource energetically profitable, (iii) to allow the tool user to gain sufficient experience with the tool using task, and/or (iv) to provide exposure to socially transmitted information.”

Cognition

Tool use has long been considered a hallmark of intelligence. For example, Thorpe (1963) asserted that as long as trial-and-error learning can be excluded, tool use is insightful because it shows

an understanding of spatial and mechanical relations. The discovery of novel or sophisticated tool use often receives wide attention, partially because customary tool use is rare in the animal kingdom but plays a prominent role in our everyday life and throughout our evolution (Call 2013). Indeed, media reports frequently show up along the lines of “since tool use is intelligent, and X species uses tools, then X species is intelligent,” or “since chimpanzees use a (specified) type of tool, and X species uses the same type of tool, then X species is as intelligent as chimpanzees” (Shumaker et al. 2011, p. 212).

As already mentioned in the previous section, tool use takes many different forms in various species and does not necessarily require complex cognitive abilities. Köhler (1927), who pioneered tool-use tests in chimpanzees, cautioned that stereotyped terms like tool use are clichés that obscure the true details of animal behavior. Tool use is often described as more complex than simple object manipulation because it involves a tertiary relation between own body, goal object, and tool, but this by itself does not mean it is inherently more cognitively demanding than other behaviors (Birch 1945; Hunt et al. 2013).

One of the most intuitively appealing instances of tool use is using a stick to acquire an out-of-reach food piece (Thorpe 1963). This sort of tool use fits most definitions because the tool acts as a functional extension of the body (Seed and Byrne 2010). Many species use tools to extend their reach. Using sticks to reach for food that would otherwise be unobtainable has been reported in yellow-crowned parakeets, Goffin cockatoos, keas, New Caledonian crows, Hawaiian crows, African elephants, spectacled bears, and a host of monkeys, gibbons, and all great apes (Laumer et al. 2016; Rutz et al. 2016; Shumaker et al. 2011; Tebbich and Teschke 2013). Not surprisingly, the frequency and underlying cognition of use of reaching tools varies strongly, which has been an experimental paradigm for a long time. For example, chimpanzees are known to ignore a stick if the food is within reach, choose a stick that is sufficiently long, ignore irrelevant perceptual aspects of the stick (such as color and texture), focus on establishing contact between stick and food, and

flexibly substitute the food for any other goal item (Povinelli and Penn 2011).

Even in species that habitually use tools, experience can play a pivotal role in the development of fully functional tool behavior. Birch (1945) tested six young chimpanzees on a reaching problem. Four of them failed to use a rake to pull in out-of-reach food in the course of 30 min. They kept trying to reach the food with their arms and frequently moved the tool aside as if it was in the way. One chimpanzee accidentally brushed against the tool, after which the food moved closer. He then pulled the tool until the food was within reach. The other successful subject, who often played with twigs and branches, immediately pulled the tool and quickly obtained the food. All chimpanzees were then exposed to sticks (nonfunctional rakes), which they often played with and manipulated, even in the form of poking other chimpanzees and the experimenter. After 3 days, they were tested on the same problem. All six chimpanzees used the tool to rake in the food in 20 s or less. They were also able to use a regular straight stick to retrieve the food, although with more difficulty. When confronted with food in a pipe, three chimpanzees successfully inserted a stick to push it out. This shows their flexible behavior, because although the same objects functioned as a tool (the stick), the required action was the opposite of how they retrieved the food in previous trials. Such reorganization of experience into functional relations is commonly viewed to be at the center of insight, which goes beyond trial-and-error learning (Emery 2013; Köhler 1927; Thorpe 1963).

The goal object does not have to be out of reach for tool use to be advantageous. A tool is a useful way to explore an object if physical contact is best avoided. Chimpanzees (Povinelli et al. 2010) and New Caledonian crows (Taylor et al. 2012) use tools to explore aversive stimuli such as rubber snakes, or to retrieve food that is within reach when positioned next to such stimuli. At least primates, and possibly many other species, include tools into their body schema after sufficient experience, meaning they represent tools as extension of their own limbs. Despite this representation, they use tools in manners they would

Nonhuman Tool Use, Fig. 2 A rehabilitant chimpanzee pokes a small fire with a piece of straw. This exemplifies that using tools in potentially dangerous situations can be advantageous. Reprinted from *Current Biology*, 20, Seed, A. M., & Byrne, R. W., Animal tool-use, R1032-R1039, Copyright (2010), with permission from Elsevier. <http://www.sciencedirect.com/science/journal/09609822>

not use their arms, which has also been an important aspect in human evolution (Povinelli et al. 2010). Using tools to explore fire is one example (see Fig. 2).

Tufted capuchin monkeys are habitual tool users and, like chimpanzees, are able to push a tool into the end of a tube so the contained food falls out on the other side. A popular variation of these tests is the trap tube, which is a transparent horizontal tube with a trap on the bottom that would capture the food if it were moved there. Success thus depends on avoiding this trap and moving the food out on the other side of the tube. It relies on understanding the relationship between the agent, food, tool, and trap, which adds another dimension (the trap) to other kinds of reach tool use. Most capuchins and chimpanzees failed this task, and the successful ones seemed to learn to simply avoid the trap. This

strategy remained present when the tube was inverted so that the trap was nonfunctional because it was at the top of the tube. Many researchers therefore concluded that capuchins and chimpanzees lack the kind of causal understanding that is often assumed to underlie their tool use (Seed et al. 2011).

However, it subsequently became clear that such results do not unequivocally point to that conclusion. Apes performed better when given a thinner tool that allowed them to pull instead of push, when only one tool was present, when the tool was not pre-inserted, and when they could use their fingers instead of tools. Adult humans also continued to avoid the trap in the inverted trap-tube, showing it to be a poor control test. Solving this test is not limited to primates. Rooks, a non-tool using corvid species tested with pre-inserted sticks, and a woodpecker finch also passed. It is possible that the successful subjects relied on arbitrary cues because it took them tens of trials to reach criterion, which allows for plenty of trial-and-error experience (Seed et al. 2011). A reduction in number of trials to reach criterion is not indicative of qualitatively different cognitive abilities (Povinelli and Penn 2011). Another trap was introduced in various configurations, such that the food was between both traps and sometimes had to be pushed into a trap for it to be retrievable. Three New Caledonian crows and a rook passed this test, as did a chimpanzee on the non-tool version, which suggests they were using relevant causal properties rather than arbitrary cues to reach a solution (Seed et al. 2011). Only 3 out of 14 woodpecker finches solved the initial task with two traps, but none performed above chance on the transfer task (Tebich and Teschke 2013).

Seed and colleagues (2011) classify knowledge about object properties into three kinds. Perceptual knowledge is limited to object properties that are immediately available to the senses. Solving the trap tube has to be learned based on perceivable properties that have no causal connection to the task itself, and transfer to novel tests is only possible if some learned cues remain present. Structural knowledge involves encoding functional properties such as continuity and solidity.

It allows for transferring between configurations of the trap tube because the causally relevant principles remain, and a change in perceptual features does not matter. Subjects that passed the trap tube with two traps and its transfers have such structural knowledge. Symbolic knowledge is based on seemingly arbitrary cues having meaning that cannot be reduced to perceptual or structural knowledge. An opaque trap tube where the position of the trap can be inferred from a painted line is an example, which appears to be absent in animals, and starts developing in children at 6 years or older.

In contrast to Birch's (1945) chimpanzees that could use a tool to push out food after having used a tool to pull food from a tube, others fail to do this in the trap tube test. One possible explanation is that the number of elements and their relational complexity simply becomes too high when the trap is introduced (Povinelli and Penn 2011). Goffin cockatoos, which are not known to use tools in the wild, were trained on using two tools, each only functional for one type of apparatus. When given the choice between a functional tool and a non-preferred food, they chose the tool, with which they could retrieve a preferred food item from the apparatus. They instead took the non-preferred food if the tool was of the wrong type for the presented apparatus, such that it could not be used to retrieve the preferred food from within. However, when presented with both tools and both apparatuses, with a different food type in each, they failed to choose the tool that would be functional on the apparatus that contained the preferred food. This suggests that the cockatoos failed to simultaneously consider six dimensions, possibly leading to a relational complexity too great for their attention and/or working memory (Laumer et al. 2016).

One method for quantifying tool-use complexity is categorizing its relational and spatial aspects. Frigaszy and Cummins-Sebree (2005) identify five such properties: (1) number of spatial relations between external elements (e.g., raking in food involves only one relation, that between stick and food); (2) positioning of objects in relation to body and environment, with body-centered actions being more direct (e.g., placing a cup on a

saucer is relatively indirect and difficult compared to just picking it up); (3) precision required for action, with more precise actions being more complex (e.g., hitting a log with a mallet is easier than hitting a nail with a hammer); (4) temporal nature of control, with static actions not requiring any action to maintain a produced relation, and dynamic relations requiring continuous action and monitoring (e.g., a tool can no longer be manipulated once thrown, but raking in food is a dynamic action); and (5) temporal order of production, with concurrent relations requiring more divided attention, coordination, and working memory than sequential relations (e.g., hammering while holding the nail against the substrate is typically more difficult than first securing the nail into the substrate and then hammering it). Systematically varying experimental settings can uncover the properties that influence performance on a given tool task.

Like the cockatoos, chimpanzees and orangutans consider several dimensions of tool-use tasks and take a functional tool over food if it can be used to obtain better quality food (Osvath and Osvath 2008). They even do so with foresight and in the absence of a visible reward, which was often regarded as a uniquely human trait (Oakley 1956; Seed and Byrne 2010). In contrast to these apes, Goffin cockatoos are not known to be habitual and proficient tool users in the wild. Cockatoos may have sufficient general cognitive capacities to succeed on such tool-using tasks. Specifically, they have high behavioral flexibility, inhibitory control, and sensorimotor skills (Laumer et al. 2016).

There are numerous additional examples of non-tool using species performing at similar levels as tool specialists. For example, after their surprising performance on the double trap tube, rooks were tested on a series of tool-use tests. Following training to drop a stone down a tube to collapse a platform containing food, they chose stones according to the size of the tube, used sticks for dropping when they were heavy and for pushing when they were light and long, and even used and manufactured hook tools to retrieve a bucket with food. These results largely mirror those of their tool-using cousins, New Caledonian crows

(Emery 2013). This behavior follows the definition of insight because it is “spontaneous (i.e., not the result of explicit training or trial and error), novel (i.e., not performed before), functional (i.e., solve the problem and be goal-directed), and built from previous, untrained, similar behavior (i.e., not produced from copying earlier learned responses, but adapting previous behavior into new actions)” (Emery 2013, p. 80). However, what insight is – if it indeed reflects a true cognitive mechanism – and what qualifies as sufficient evidence remains a hotly debated topic (Call 2013; Hunt et al. 2013; Jelbert et al. 2015; Seed and Byrne 2010).

In some cases, tool-using species do not even outperform their non-tool-using relatives on tasks that do not require tools. For instance, woodpecker finches did not outperform small tree finches, a closely related species that does not use tools, on two tests of physical cognition and one of reversal learning, although they did perform better on a novel operant task. Woodpecker finches still develop tool use without observing others do so, although it appears there is a sensitive ontogenetic phase during which they have to learn how to use tools or they never will. These results suggest that tool use in woodpecker finches arises from genetic predispositions, trial-and-error learning, and stimulus generalization, which overall do not result in specialized cognitive abilities because their close relatives perform at similar levels. One possibility is that their last common ancestor already had these cognitive abilities and that tool use in woodpecker finches is an adaptation to their ecological circumstances, similar to the foraging specializations of other Darwin’s finches (Tebbich and Teschke 2013).

Emery (2013) describes three lines of evidence that tool use is not necessarily associated with enhanced cognitive abilities. First, tool specialists may not perform well on tool-related physical cognition tasks. Woodpecker finches are an example of this. Second, tool specialists may perform better when a task does not involve tool use, as is the case for chimpanzees using their fingers rather than a tool to solve the trap-tube test. Third, species that do not use tools in the wild may have similar cognitive capacities as their tool-using

relatives, even when the test itself involves tool use. This can clearly be seen in rooks and Goffin cockatoos.

So how plausible is Aesop's fable of the thirsty crow? This question is difficult to answer because we don't know the context and previous experience of the crow – or even what species it was. Nonetheless, recent studies provide ample speculations. For instance, a pet blue jay regularly dropped items into its water bowl if the level was too low for drinking (Shumaker et al. 2011). The first formal experiment was on rooks, but their success might come from generalization because they already had previous experience dropping stones into a tube to collapse a platform. Unexperienced New Caledonian crows did not spontaneously drop stones into a water-filled tube containing a floating food item. All other experiments therefore started with training subjects on the collapsible platform apparatus. Both species stopped dropping stones once the reward was within reach, showing goal-directedness. This was also evident in Eurasian jays, another corvid species, which preferentially dropped stones into baited rather than non-baited tubes (Jelbert et al. 2015).

Overall, most of these corvid subjects preferentially selected large over small stones; sinking over floating objects; solid over hollow objects (which displace less water); water-filled over empty, sand- or sawdust-filled tubes; and narrow over wide tubes when the stone supply was limited. They generally failed when the functional cues were arbitrary or counterintuitive, such as dropping a stone in one tube to raise the level in another. This stark contrast suggests that corvids rely on functional cues, even when noncausal cues give similar visual feedback. Nonetheless, immediate feedback likely enabled subjects to learn quickly, because the proportion of correct initial choices was not above chance. They also seemed to prefer solid objects, even when solidity did not matter as in the platform-collapsing apparatus. Five-year-old children perform at similar levels. In conclusion, stone-dropping behavior in this paradigm is largely explained by object bias, visual feedback, and rapid learning based on causal cues (Jelbert et al. 2015). Aesop's fabled

crow might thus have been less insightful than described.

Conclusion

Tool use is no longer a defining characteristic of humans. It is increasingly often discovered to take novel forms and functions in a wide range of species. There are of course differences between humans and nonhuman animals in how they use and represent tools, but these differences are not as pronounced as regarded some decades ago. Animals only rarely use tools to make tools, seldom cooperate in using or making tools, and power their tools only with gravity and their own metabolic energy (Shumaker et al. 2011). The proposed differences mostly lie in humans having more developed representational abilities, executive functioning, sensorimotor abilities, dexterous manipulation, and collaborative culture (Call 2013; Frigaszy and Cummins-Sebree 2005; Hunt et al. 2013; Povinelli and Penn 2011; Seed and Byrne 2010). Nonetheless, both difference and similarities between species are informative, without the need to redefine tools and mankind or accept other species as humans. If we truly want to understand tool use, we need to clearly define and describe it and look at the ecology, evolution, and cognition of a wide variety of species.

Non-primate Mammal Sperm Competition

Julián Santiago Moreno

[Interindividual male gamete rivalry in oocyte fertilization](#); [Post-copulation strategies in oocyte fertilization](#)

Definition

Post-copulatory scenario in which the sperm of males of polygamous species competes within the female genital tract to fertilize the oocyte.

Introduction

In many non-primate mammalian species, females may mate with more than one male. According to the sperm competition theory, the reproductive success of the males of such species depends on both the magnitude of inter-male

rivalry and covert sperm competition. When the ejaculates of two or more males must compete to fertilize a set of ova, the quality of the sperm they carry becomes of great importance. The transfer of large numbers of spermatozoa in competitive situations is an effective strategy; males that transfer more sperm per ejaculate, or who copulate more often, are more likely to sire offspring. Usually, males of polygamous species have large testes and produce ejaculates with many sperm cells. Sperm competition also acts as a selective force driving evolutionary change in sperm morphology and function. The degree of sperm pleiomorphy shown by a species varies according to the degree of sperm competition its behavior entails.

Sperm Competition in Polyandrous Species

The sperm of some individuals appears to enjoy advantages over that of their rivals. This is particularly important in polygamous species that practice polyandry, including rodents and many ruminants. Females can benefit from polyandry since males successful in both pre-copulatory (e.g., intra-sexual fighting) and post-copulatory (sperm competition) sexual selection are more likely to sire high-quality offspring.

In many species in which female preference is important in mate selection, males with large and conspicuous sexual selection traits are commonly favored; indeed, male ornaments, to which female attention is paid, play a significant role as part of pre-copulatory strategies. In polygynous species, mate selection focuses mainly on the role played by weaponized male secondary sexual characteristics. Antlers and horns are employed in the pre-coital strategies of several ruminant species, the males using them to establish their dominance. A relationship between horn development and seasonal changes in breeding activity is clearly evident, with wild ruminants attaining maximum horn development just before the onset of the breeding season. However, this weaponry also appears to be a sensitive indicator of genetic stress and a means of providing signals of male vigor to

females. The role of symmetry, a characteristic of genetic vigor, in the attraction of females is well established in many species. Thus, dominant males with larger and more symmetrical horns are likely to be selected for reproduction via their improved access to receptive females, but also via the latter's preference for them.

In some species in which females mate with more than one male, the *sperm competition theory* indicates that male reproductive success depends upon the magnitude of inter-male rivalry and covert sperm competition (Preston et al. 2003). Reproductive success is thus a function of both pre- and post-copulatory strategies. Certainly, larger weaponry is often associated with better sperm quality in polygynous ruminants. Horn and antler size in wild ruminants such as ibexes and red deer is associated with testis size and sperm velocity, and in ibexes, males with the largest and best-developed ornamentation produce semen with a larger proportion of motile spermatozoa and a smaller number of sperms showing primary morphological abnormalities (Santiago-Moreno et al. 2009). This provides some evidence to support the phenotype-linked fertility insurance hypothesis. It may even be that wild bovid and cervid females use horn/antler quality as an index of male genetic and sperm quality. However, when the ejaculates of two or more males compete to fertilize a set of ova, the quality of the sperm they carry becomes of great importance. The transfer of large numbers of sperm is guaranteed by ejaculates with high sperm concentrations, and males of polygamous species usually have large testes and produce ejaculates with high sperm concentrations (e.g., the testis size/body size ratio is higher in promiscuous dogs [*Canis lupus familiaris*] than in monogamous wolves [*Canis lupus*] [Asa et al. 2016]). Successful competition between rivals at the site of fertilization then depends on the number of spermatozoa that enter the oviductal isthmus (sperm reservoir), the proportion of spermatozoa that undergo capacitation and the proportion that respond to ovum-associated signals.

In mammals, sperm length has been positively correlated with maximum sperm velocity.

Although larger sperm heads might be thought a handicap to rapid swimming, several reports show that sperm with longer heads may swim faster (Gomendio and Roldan 1991; Malo et al. 2005). In scenarios of sperm competition, this may afford them a competitive advantage, as may the ability of sperm to maintain high concentrations of intracellular ATP (Tourmente et al. 2015). Indeed, differences in the intensity of sperm competition appear to influence the sperm morphometric variables of wild polygamous ruminant species. For example, in mouflon (*Ovis musimon*), a species with intense polyandry, rams produce sperm with larger heads (and in greater numbers) than other Mediterranean mountain ungulates such as the ibex (*Capra pyrenaica*), aoudad (*Ammotragus lervia*), or chamois (*Rupicapra pyrenaica*). Chamois sperm, which has the smallest head dimensions and is produced in more modest concentrations, may indicate the species to be less polyandrous (Pradice et al. 2016).

Sperm competition also acts as a selective force driving evolutionary change in sperm morphology. The degree of sperm pleiomorphy shown by a species varies according to the degree of sperm competition its behavior entails. Although this is more evident in birds, monogamous mammals (e.g., species of Felidae except for the lion) usually have a higher rate of sperm morphological abnormalities than do very polygamous species, such as many ruminant species.

Sperm variables in polygynous ruminant species in which polyandry plays an important role are related to horn/antler characteristics, revealing a likely strong genetic influence. The social environment may, however, also affect these variables. The social status of an animal varies over its lifetime, even though it might possess high-quality weaponry. The social environment affects physiological variables, such as plasma testosterone and cortisol concentrations, that in turn influence spermatogenesis and sperm maturation and subsequently sperm quality. An impact on seminal plasma composition, e.g., on the seminal fluid proteome composition, might also be expected. Indeed, in some rodents the plasticity of different ejaculate components may be strongly influenced by social environment (Ramm et al. 2015).

Conclusion

Reproductive success in polyandrous species is a function of both pre- and post-copulatory strategies. With respect to the latter, sperm competition plays an important role and is dependent on sperm concentration, sperm velocity variables, and the proportion of sperm produced with morphological abnormalities.

Nonverbal Indicators of Dominance

Kristofor McCarty

Department of Psychology, Northumbria University, Newcastle upon-Tyne, Tyne and Wear, UK

Synonyms

[Fighting ability](#); [Formidability](#)

Definition

Dominance in large part is having power or influence over others. An important part of negotiating access to resources, be it food or mates, throughout the animal kingdom and ancestral humans is/has been achieved through physical force, particularly between males. For example, men who repeatedly win fights and contests against other men (intrasexual selection) are often revered in society, and their status within the group is elevated (Hill and Hurtado 1996). This functions as a deterrent to potential competitors from challenge and is known as *physical dominance*, which will be the focus of this section.

Introduction

The ability to make accurate assessments of physical dominance in species with aggressive social interactions is of particular importance as it can ultimately fall within the realm of natural selection. People who have the potential to inflict serious or even fatal physical harm is a strong selective force and it makes sense that our perceptual system has evolved cognitive mechanisms in which to make dominance judgments based off a number of cues.

This section will focus on male cues of dominance as males have productively limited access to mates and have engaged in intra-sexual

conflict, be it one-on-one, or in a coalitional sense (e.g. war) (Keeley, 1996).

Static Cues

It is well known that humans have highly specialized neurological structures to quickly extract information from faces as these hold the key to many social interactions such as the identification of emotions, sex, age, and attractiveness. Aggressive confrontations are often acutely time sensitive and given our affinity with faces, it makes them an ideal structure in which to assess dominance.

Intrasexual selection is thought to have been a strong selective pressure on men's bone structure resulting in thicker skulls, pronounced brow ridges, and more robust mandibles in order to provide better protection from damage (see Puts 2010 for a review). The expression of men's facial structure is thought to be at least in part determined by prenatal testosterone exposure in utero with higher exposure leading to more exaggerated expression of such traits. At puberty these structures are activated by the surge of circulating testosterone thus contributing to sex differences in appearance. Prenatal testosterone exposure also leads to many other organizational effects on men such as increased physical strength and cardiovascular fitness – all of which can be attributed to the ability to fight.

Research has found that exaggerated masculinized features lead to higher ratings of dominance by both men and women (e.g., Neave et al. 2003) and that people are generally accurate when judging strength and formidability (fighting ability) from men's faces (Sell et al. 2009). Furthermore, men with masculinized facial structure typically have higher circulating testosterone (Penton-Voak and Chen 2004; Roney et al. 2006) which is attributed to more dominant behavior (Mazur and Booth 1998).

A rapidly growing area of research has begun to document how the ratio between the width and height of a face (fWHR – bizygomatic width divided by upper facial height to be precise) is correlated with many dominance traits,

particularly aggression. If a man has a high fWHR (they have a wider face), then this seems to be associated with more aggressive reactions to a perceived slight by others, greater sporting penalties resulting from aggressive fouls, as well as socially aggressive behavior such as being self-interested and performing more violations of trust in economic games (Haselhuhn et al. 2015). Furthermore, men with higher fWHR's have also been found to have more circulating testosterone (Lefevre et al. 2013) which might be a mediating factor in explaining these behaviors. Interestingly, these associations appear to be exclusive to men and no relationships are found between fWHR and dominance-related traits in women. Taken together this suggests fWHR is a cue to dominance in men.

Aside from facial structure, another source of dominance information is a man's facial hair. Facial hair does not hold any clear survival value, it is not usually present in women or children, and its expression is dependent on testosterone (Saxton et al. 2015). From an intersexual point of view, facial hair growth does not relate clearly and consistently to ratings of attractiveness. However, dominance ratings show a positive linear pattern with facial hair prevalence indicating that beard growth might have primarily evolved via intrasexual means.

Perceptions of dominance are subject to individual differences, particularly in relation to the observer's own dominance status. Studies have shown that a man's self-rated dominance affects his ratings of faces manipulated for dominance. Shorter men are more sensitive to cues of dominance and rate men's faces as more dominant than taller men do (Watkins et al. 2010, 2013). This has been explained in terms of allowing less dominant men to avoid conflicts that might be costly. However, this moderation effect does not hold true for all studies and there is some debate as to whether these effects are in fact robust (Lefevre and Lewis 2014).

Another indicator of someone's physical dominance status is of course their size and build. Men have around 75 % greater upper body muscle mass than women and are typically taller and heavier with broader shoulders (see Sell

et al. 2012). These traits are easily observable and are perhaps one of the most direct ways in which to assess physical dominance. The reason men have greater upper body muscle mass than women is that this is the primary mechanism for inflicting damage, be it grappling, choking, or punching. As expected, when observers are shown static photographs of men's torsos they are able to quite accurately gauge that man's upper body strength however, this relationship does not hold true for his lower body strength suggesting our perceptions are engineered for detection of fighting strength (Sell et al. 2009).

Dynamic Cues

There are numerous occasions where the static features on which we rely on to make dominance judgments might be concealed, for example, when it is dark, the person is wearing clothing or they are at a distance. As these factors are common in everyday life and the costs of misjudging someone's fighting ability may be grave, we might predict that humans have also developed ways in which to assess dominance using other mediums.

The ability to perceive motion is an ancient information channel and was likely developed before our eyes had sufficient resolution to interpret static detail. Motion is detected and processed very quickly and likely evolved as a result of natural selection in order to detect predators. Several strands of evidence support the hypothesis that movement provides reliable information about an organism's physical condition as unlike many static constructs, movement is very difficult to fake or conceal. In the animal kingdom, for example, it is used to size up competitors before serious intra-sexual conflicts (for example, deer and some species of fish, see Sell et al. 2012 for a review).

The ability to record human movement with sufficient control (for example, removing structural confounds like facial attractiveness and body size) was developed in the 1970s by Swedish psychologist Gunnar Johansson and are known in the literature as point-light displays (PLDs). PLDs are comprised of an array of dots that

typically represent the major joints and structures of the body and when viewed as a static frame, people have trouble interpreting what they are or represent. However, when they start moving a vivid representation of a person's motion.

By observing only very brief presentations of PLDs depicting walking (as it is a motion we see every day), observers are able to resolve the sex of the walker with accuracy (typically in the region of 70 %). A typical male walk involves greater lateral shoulder sway and very little hip movement, whereas the opposite is true of a typical female walk (Troje 2003).

Raters give equivalent answers irrespective of whether they are asked if a PLD is of a female walker or a feminine walk. In contrast, when asked whether a walk is masculine versus whether it is a male walk, a disconnect occurs and observers will report a walker to be male much earlier in the continuum (between neutral and extreme male walk) than to assign the walk as "masculine." This is thought to be attributed "precarious manhood," a term that suggests simply being a man is quite a different concept to being a *real man* (i.e., being masculine) (Kozlowski et al. 2016).

The composition of PLDs means that facing direction is absent as there are no depth cues. When observers are asked the sex and facing direction of a sex neutral, or male walk, they will typically default to reporting that walker as walking toward them. In contrast, obvious female walkers are more likely to be perceived as walking away from the judge. Furthermore, sex neutral walkers are typically judged as being male. This is thought to be a perceptual failsafe as misjudging a male for a female and/or their facing direction may be risky. Men seem to be particularly sensitive to this effect and report extreme male walks to always be walking toward them. This again fits with a threat detection hypothesis as these cues are more relevant to them and may inform them of potential conflict (Schouten et al. 2011).

All of these factors indicate that observers have quite specific perceptions of dominance based solely on walking gait, and we have evolved cognitive mechanisms that help us size up how

dominant a man is, and have built in failsafe's to avoid misperception of facing direction. However, research to date is lacking in evidence that informs us how accurate people's perceptions are, that is, do dominance ratings track the actual dominance status of the walker?

A separate body of research has documented how body postures and gestures lead to perceptions of power and dominance (and even lead to greater feelings of power in the poser) although these judgments have primarily been attributed to more social dominance and leadership rather physical dominance. For example, when observing political candidates, key movement parameters that lead to increased perceptions of (social) dominance are more expansive body postures and gestures as well as greater movement frequency (Koppensteiner et al. 2016). While these ratings are judged in more of a social dominance context, these perceptions are likely to be rooted in the detection of physical dominance. The size of a person is a major factor in how dominant they are perceived to be, and larger men are generally more dangerous than smaller men so making yourself look larger using expansive gestures and posturing is likely to lead to increased dominance ratings.

Conclusion

Intrasexual competition has likely been a very salient selective force in humans, particularly for men. This led to the development of increased aggression, greater upper body muscle mass in order to deal damage, and to stronger, thicker bones to help limit damage incurred in fights. The risk of misjudging a potential rival can lead to serious injury or even death, and research indicates we can call upon a wealth of cues in order to make our assessments from static cues in the face and body as well as more dynamic cues in motion we see every day such as walking gait.

Taken together, the evidence detailed above indicates our perceptual system has evolved cognitive mechanisms in order to assess the dominance status of another person and keep us out of danger from potential threats.

Non-Western Homosexuality

Konstantin O. Tskhay and Nicholas O. Rule
University of Toronto, Toronto, ON, Canada

Synonyms

Sexual expression; Sexual orientation

Definition

Same-sex attraction outside of Western Europe and societies principally characterized by its colonial legacies (e.g., North America).

Introduction

Sexual orientation and homosexuality have been most prominently discussed in Western political and cultural spheres since the late nineteenth century. General understanding of same-sex attraction is thus limited by an absence of perspectives from societies with other cultural traditions and origins. For example, Western scholars and laypeople commonly describe same-sex attraction and sexual behavior using terms like “homosexual,” “gay,” “lesbian,” and “bisexual,” these labels and concepts may not even exist among people living in the cultures to which they are applied (e.g., Nanda 2014). This entry reviews how same-sex attraction might manifest in cultures not informed by Western cultural, social, and linguistic traditions.

The Multitude of Same-Sex Attractions

Western conceptions of sexual orientation typically employ certain linguistic and culturally

normative mental structures to generate representations of same-sex attraction and sexual behavior. Rarely do people in Western societies consider other expressions of same-sex attraction that may be more prevalent in other cultures (see below and Bailey et al. 2016 for examples). The term “same-sex attraction” is therefore a preferred means of describing same-sex relationships because it successfully summarizes the phenomenon of interest while subsuming various manifestations of its expression.

Indeed, although “gay men” and “lesbian women” may not necessarily exist in non-Western cultures *per se* (Blitzer 2011), expressions of same-sex attraction may exist worldwide. Scholars examining the prevalence of same-sex attraction have estimated that approximately 1.5–5 % of the contemporary world’s population is attracted to other members of the same sex (Smith et al. 2003; VanderLaan et al. 2013; Whitam and Marthy 1986). Given a large enough population, then, individuals oriented toward same-sex attraction should emerge though they may express this differently from one culture to another.

For example, *hijras* in South Asian cultures (Nanda 1998), *berdaches* in Native American cultures (Callender et al. 1983), and *fa’afafine* in Samoa (Vasey and VanderLaan 2014) all express nontraditional sexual identities that may or may not include same-sex sexual behaviors. Yet each case represents a relatively different expression of same-sex attraction and gender identity. Whereas *hijras* and *berdaches* occupy largely spiritual and religious roles that symbolize unification of male and female (exemplified in part through crossdressing), *fa’afafine* men are typically raised and socialized in feminine roles due to their more feminine childhood mannerisms and thus evidence greater pragmatism (Bartlett and Vasey 2006).

These differing expressions highlight two interesting phenomena. First, same-sex expressions in non-Western cultures often rely on “switching” between masculine and feminine roles such that the individual almost transitions in gender (e.g., *hijras*; see Tskhay and Rule 2015). Second, non-Western same-sex expressions

largely stem from iterations on defined gender roles. For example, *fa’afafine* tend to be feminine men who have sexual relations with masculine men; it is rather unlikely that two *fa’afafine* would have sexual relations with each other (Bailey et al. 2016). Therefore, even when same-sex attraction is commonly acted upon, its expression still resembles the heterosexual sexual behavior typical between men and women (Tskhay and Rule 2015).

Conclusion

In sum, same-sex attraction appears to be a relatively universal phenomenon, though its expression may vary greatly from culture to culture. Its varieties of expression are clearly shaped by cultural norms, religious traditions, and practices. However, in most cultures, same-sex attraction still follows structures inspired by more demographically common gender roles, such as heterosexual attraction and behavior.

Behavior patterns; Common knowledge; Public behaviors; Rule; Social norm; Standard

Definition

Norms are expectations stating that something should or must be the case or socially shared definitions of the way people do behave or should behave. From a sociological perspective, social norms are informal understandings that govern the behavior of members of a society.

Norms have obtained a great deal of attention in the social sciences, such as anthropology, economics, political science, sociology, and psychology. This article will introduce this item from the perspective of evolutionary psychology. Two main topics will be touched in this review: the emergence of evolutionary social norms and the social norms-marketing campaign resulting from the connection between social norms and behaviors.

The Emergence of Evolutionary Social Norms

Being different from the institutional norms, which are formed and enforced by certain individuals (usually the leader of group) or institutions, and voluntary norms, which emerge by the voluntary agreement among group members, the evolutionary norms and the measures for their fulfillment are not explicitly stated (Karl-Dieter 1982). The emergence of evolutionary norms has

been described by several models, among which the emergence of cooperative and altruistic behaviors have been discussed and explored extensively.

The Kin Selection Model

Developed from a biological approach, the Kin selection model indicated that the degree of genetic relationship played an important role in predicting the selection of altruistic behaviors. According to the genetic relationships of the organisms involved, the altruistic behaviors could be explained in terms of natural selection: the organism would provide help to their relatively close kin in order to ensure the successful delivery of their genes. The kin-selection model predicted that altruistic behaviors depended much on the degree of kinship between giver and receiver.

One study (Rachlin and Jones 2008) indicated individuals would give significantly more money for the benefits of their relatives than for the benefits of nonrelatives at almost every social distance. These results were in line with kin-selection theory and supported the important role of genetic relationship in individual's altruistic behaviors.

However, the kin-selection model cannot explain why individuals show cooperative behaviors toward strangers in some cases. It is obvious that strangers could not be helpful for the organism's reproductive success. Another model of "reciprocal altruism" (Trivers 1971) was proposed to explain this phenomenon.

The "Reciprocal Altruism" Model

According to models of "reciprocal altruism" (Trivers 1971), the chance of evolving for the altruistic behaviors was little in random pairings. However, the evolving chance would increase in a social framework because individuals could benefit from building reputations of being altruistic to

other, which would be beneficial to those who perform altruistic behaviors in the long run. Consequently, the altruistic behaviors would also be favored by natural selection in such cases. In the models, Trivers (1971) discussed three instances of altruistic behaviors – behavior involved in cleaning symbioses, warning cries in birds, and human reciprocal altruism – and further explained their evolutionary mechanisms. As for the human reciprocal altruism, Trivers suggested that "friendship, dislike, moralistic aggression, gratitude, sympathy, trust, suspicion, trustworthiness, aspects of guilt, and some forms of dishonesty and hypocrisy" could be explained as important adaptations to regulate the altruistic system. Each individual human was seen as possessing altruistic and cheating tendencies at the same time, the expression of which was "sensitive to developmental variables that are selected to set the tendencies as a balance appropriate to the local and ecological environment." According to Trivers, by properly identifying the other agents in a social framework reputation could influence behaviors of the agent: people who show altruistic behaviors would be treated altruistically and people with a reputation of being indifferent would be treated indifferently. Trivers' opinions have been supported empirically by research (Griskevicius et al. 2010).

Simulating the Emergence of Evolutionary Social Norms with Play Games

Based on the Nash equilibrium, quite a few play games were developed to explore the emergence of social norms, especially the cooperative and altruistic behaviors.

By simulating the norms game and the meta-norms game, Axelrod (1986) explored the dynamical processes of the social norms formation. Based on the simulation of norm games, he further proposed the mechanisms that served to support the partially established norms such as meta-norms, dominance, internalization, deterrence,

social proof, membership, law, and reputation. Among the eight mechanisms, Axelrod suggested that reputation and dominance could serve in the origin and content of norms. Axelrod stated "Dominance can work because if only a few very powerful actors want to promote a certain pattern of behavior, their punishment alone can often be sufficient to establish it, even if the others are not vengeful against defections." Actually this conclusion can be confirmed that many norms complied with by people in daily life served the powerful. In line with Trivers' model (Trivers 1971), Axelrod (1986) also believed reputation was an important mechanism of social norms emergence, especially the cooperative or altruistic behaviors.

With the Trust Game, which is role-contingent and like one-sided Prisoner's dilemma, Bicchieri et al. (2004) simulated the emergence of trust and reciprocation. Their study showed as a result of the repeating interaction of several different strategies, which were conditional ones, the norms of trust/reciprocation could come into being and became the dominant observed behavior. This research enriches Trivers' model by describing the emergence of trust/reciprocation based on several, but not single, behavioral strategies.

Skyrms (1996) and Alexander (2007) explored the norms emergence from the cognitive and structured interactions approaches. With a variety of play games, such as the Prisoner's Dilemma, the Stag Hunt, Divide the Dollar, and the Ultimatum Game, they described how the moral norms came into being under different game situations. Both of them emphasized the simpler mechanisms or leaning rules, such as "imitate the best" or best response, in the different norm-formation games. They pointed out agents would rely on their learning rules to select the appropriate strategy. Being different with the model of Bicchieri and his colleagues, who emphasized the several strategies, Skyrms and Alexander believed norms were developed on the basis of single strategy. It is noticeable that both of them emphasized the role of structured interaction in the norms formation and they made some refinement on this structural approach by

differentiating two different kinds of networks: interaction network and update network.

The Spread of Social Norms

How do the social norms spread and change in real life? A vast literature support that social norms are communicated through social interaction. For example, face to face communication constitutes an important approach for the formation and spread of norms (Chwe 2001). Being consistent with Sherif's group norm theory, which states that social norms of prejudice "are the products of contact with members of a group; they are standardized and become common property within a group," one study (Monteith et al. 1996) indicated that participants' prejudiced opinions concerning gay men and blacks decreased significantly under the activation of non-prejudiced opinions made by a confederate.

In addition, Paluck (2009) emphasized that individuals could shape and were shaped as well by their immediate social surroundings, "alone, people become aware of ideas...in groups they [become] aware of other people's awareness [and]... their endorsement creates another vector of social influence." His study (Paluck 2009) suggested the group listening to an emotionally engaging radio drama could result in the change and spread of social norms due to its socially interactive nature. Paluck believed the heated discussion during and after the radio drama listening "creates another vector of social influence" on listeners and "contributed further to socially shared cognition, which is the basis for a social norm."

The Influence of Social Norms on Individual's Social Behaviors

A variety of research supported the influence of individual's normative beliefs on their social behaviors, or in other words, social norms spurred individual's conforming behaviors.

For example, a cross-cultural study (Zou et al. 2009) proved social norms, or the perceived

cultural consensus, could powerfully predict individual's social judgement. A current research (McGuire et al. 2017) explored the influences of group norms on the behavior of resource allocation among children with an age from 8 to 16 years. The result indicated that participants showed the most ingroup-biased resource allocation under the condition of both the ingroup and outgroup peer norms being competitive. In addition, with years when allocating intergroup resources individuals could consider both ingroup and outgroup norms simultaneously. However, only older children changed their reasoning to justify their allocation according to group norms.

In addition according to the information, delivering social norms can be classified to different types, such as descriptive norms, injunctive norms, and situational norms. Different social norms could make particular effects on the individual's social behaviors.

By informing individuals of what behavior is appropriate or adaptive in certain situation, descriptive norms, which refer to how most people behave in a specific situation (Cialdini et al. 1991), could guide individual's private and public behaviors as well. With two experiments study, Goldstein et al. (2008) indicated descriptive norms could effectively motivate participants to engage in the activities of environmental conservation. Especially when people were confronted with threat or danger, they would be motivated significantly to go along with the social environment (Griskevicius et al. 2006).

In addition to the descriptive norms, the focus theory (Cialdini et al. 1991) proposed another type of social information called injunctive norms, which refer to the individual's perceived degree of social approval /disapproval for certain behavior. According to focus theory, the two types of norms are highly relevant to different fundamental human goals. The information provided by descriptive norm is highly relevant to the intrapersonal goal of behaving accurately or choosing correctly. However, the injunctive norm is especially relevant to the interpersonal goal of establishing and maintaining good social relationship by winning the social approval. The main hypotheses above of focus theory have been

supported by the empirical evidence (Jacobson et al. 2011).

Another type of social norms is the situation norms, which refer to "knowledge or mental representations of appropriate behavior that guide behavior in a certain situation or environment" (Aarts and Dijksterhuis 2003). With three experiments, the study (Aarts and Dijksterhuis 2003) suggested that not all situational norms were able to guide individual's social behavior directly. Only those well-established situational norms, which can be regarded as associations between specific situations and normative behavior in memory, could effectively play the role of activating the normal behaviors under certain situations.

Finally, the emotion also plays a role in the connection between social norms and individual's compliant behaviors.

One study (Colombo 2014) explored the role of emotion in motivating social norm compliance. Contrary with resentment hypothesis (Sugden 1998) and hedonistic hypothesis (Fehr and Camerer 2007), Colombo believed that caring, but not resentment and pleasure, might be the source of feeling emotions and the ultimate motive of norm compliance. On the other way, social norms can also make an effect on people's feeling, such as regret. Based on the classic action-effect, which described the phenomenon that individuals regretted actions resulting in negative outcomes more than they did inactions bringing about the same negative outcomes (Kahneman and Tversky 1982), a recent research (Feldman and Albarracín 2017) supported that "negative outcomes resulting from action are regretted more than when resulting from inaction." With four experiments, their study indicated when social norms were for inaction the action-effect was much stronger and the action-effect would be weakened and even reversed in case of the social norms were for action.

The Social-Norm Marketing Campaign

A large number of programs, which were called social-norms marketing campaign, have been carried out based on the two consistent conclusions:

most people tend to overestimate the prevalence of many destructive behaviors, and individuals usually use their perceived norms as a standard to guide their own behaviors. By delivering the normative information that the occurrence of deleterious behaviors is less than most people think, this campaign aims at correcting people's misperceptions and reducing the occurrence of undesirable conducts, such as excessive drinking, drug abusing, disordered eating, and littering and waste of resources.

Based on social norms-based social marketing campaign, most interventions decreased the level of alcohol consumption (Neighbors et al. 2004) and gambling addiction (Neighbors et al. 2015) on campus successfully. However some research (Granfield 2005) failed to confirm the effectiveness of this approach.

One study (Schultz et al. 2007) provided a potential explanation for the mixed results of the intervention programs. Their research (Schultz et al. 2007) demonstrated delivering high-energy-consuming households with descriptive normative information about the average level of home energy usage in the neighborhood significantly decreased energy consumption. On the contrary, the same information resulted in an improvement of energy consumption for low-energy-consuming households. However, when combining the descriptive normative information with an injunctive message of approval, the low-energy-consumption family would decrease their consumption at the desirable low rate, rather than increasing significantly toward the mean.

Conclusion

The emergence of evolutionary social norms has been explained and explored extensively. In addition to the models of "kin selection" and "reciprocal altruism," other models were developed by simulating the forming process with different play games. Social norms can be spread by face to face communicating and social media as well. A vast amount of literature supported that social norms could spur individual's complying behaviors. By correcting individual's misperception of social norms, quite a lot interventions called social

norms-marketing campaign have been carried out to reduce individual's deviant behaviors although the specific mechanisms still await for further exploration.

Definition

Biologically speaking, nuptial gifts are contributions – other than genetic materials – provided by a donor to a recipient during courtship. These materials are often designed to improve the fitness of the recipient, but can also be of little value or even no value (Lewis et al. 2014). In modern human mating, nuptial gifts exist most notably in the form of engagement and wedding rings.

Introduction

Several species of insects, birds, and mammals are known to give or exchange a diverse range of gifts during courtship or copulation including, but not limited to: nongametic organic materials, food items, and apparently worthless tokens (LeBas and Hockham 2005). In human mating, nuptial giving has existed for most of recorded history (Cronk and Dunham 2007). Modern human courtship often involves men offering prenuptial and nuptial gifts which are of high cost to provide, but of little or no tangible benefit to the female recipients (Sozou and Seymour 2005). Engagement rings and wedding bands are often given as examples of such nuptial gifts.

Brief History

In some cultures, traditions of bride price or bride service, which is a payment by the groom or his family for the bride, are still practiced (Anderson 2007). Also common in some cultures is the dowry, which is a payment of property, gifts, or monetary wealth transferred from the bride's family to the groom and his family. Over time, cultural practices can slowly shift between bride price and dowries, depending on the culture and the location (Anderson 2007). The specific practice of giving wedding rings dates back to early recorded history and engagement rings have been given since the Middle Ages, but only in the twentieth century have these practices become commonplace (Cronk and Dunham 2007).

Evolutionary Development and Benefits

In many taxa, nuptial gifts are known to improve several aspects of female fitness (Brockmann et al. 2012). In some specific species, however, males can replace a gift of value, such as food, with a worthless gift and females will still accept it and mate for a certain period of time (LeBas and Hockham 2005). In humans, this is arguably mirrored by the historical shift from bride prices – which transferred tangible property or money to the bride's family – to engagement rings and wedding bands, which are of relatively little inherent value to her or her family.

The above parallel with worthless gifts is not to say that engagement rings and wedding rings do not serve a purpose. Engagement and wedding rings can be used as bonding devices between partners (Cronk and Dunham 2007), and it is generally known that engagement rings are a sign of increased relationship commitment. Research has linked the quality of nuptial gifts with the overall value of the mates involved (Cronk and Dunham 2007). The amount spent on engagement rings reflects certain aspects of both male and female mate quality. Specifically, males with higher incomes spend more on engagement rings, which can indicate more resource control (Cronk and Dunham 2007). Younger women, who tend to have higher mating and fertility potential, and women with higher incomes are also given more expensive engagement rings (Cronk and Dunham 2007). These patterns indicate that investment in a nuptial gift can be a reflection of perceived male and female mate value. The connection between ring value and mate value can give women valuable information about male levels of commitment to a relationship and the extent to which he may or may not invest in her and her potential offspring (Cronk and Dunham 2007; Sozou and Seymour 2005).

Conclusion

In most taxa, nuptial gifts evolved to improve aspects of female fitness and increase the male's chances of mating, but the history of human nuptial gifts is more complicated. Varying by region,

human marriage traditions have slowly shifted from wealth transactions such as bride price and dowry, which provide tangible benefits to at least one party, to the giving of engagement and wedding rings. Wealthier males, unsurprisingly, tend to spend more money on nuptial gifts, and wealthier females with higher mating potential tend to receive more expensive gifts. Both of these patterns are consistent with the idea that the price of nuptial gifts reflects perceived mate value. Even though engagement rings and wedding bands have almost no practical utility, these gifts may provide women with clues as to a potential partner's commitment to their relationship and her potential offspring.

Definition

A book, written by Judith Rich Harris, which explores the effects of genetic influences and peer relations on personality development.

Introduction

The Nurture Assumption: Why Children Turn Out The Way They Do is a book written by psychologist and independent scientist Judith Rich Harris and was originally published by The Free Press in 1998. The book provides a well-supported

argument for Harris' theory that genes and peers influence the development of one's personality far more strongly than the way one was parented. It has been critically acclaimed by several psychologists – including Robert Sapolsky, Steven Pinker, Malcolm Gladwell, and several others – stating that Harris' provided strong scientific evidence for a profound conclusion. However, the book has also been met with negative reviews by some psychologists who argue that Harris did not include important data that contradicts the conclusion in her book (Begley 1998; Kagan 1998). A second edition of the book was published in 2009 with an extra foreword by Dr. Harris addressing the misunderstandings that many critics of the book had made (Harris 2009).

About the Book

The term *Nurture* within the title refers to the latter half of the classical “nature versus nurture” debate in psychology. In *The Nurture Assumption*, Harris addresses this debate – which asks whether personality and behavior are products of our genes (i.e., nature) or our environment (i.e., nurture) – by examining the scientific research in many areas of psychology, including developmental, clinical, social, and evolutionary psychology. Harris' examination reveals two key points: genes strongly influence personality, and although environment (i.e., nurture) also influences personality and behavior, this influence stems mostly from peers. Parents do not have a strong influence on their children's personality development.

Harris takes time to explain the dangers of inferring causation from correlation, and goes on to explain that most child psychology stems from correlational designs as opposed to experimental designs, which makes it difficult to know what is causing a child's personality and behavioral development. She goes on to cite many twin studies that illustrate the influence that genes have on personality. Genes account for approximately half of one's personality and IQ. For example, identical twins raised together in the same home are no more alike than identical twins raised apart – indicating that genes account for most of the similarities between

these personalities, and home environment plays a very small role in personality development.

The book also contains many examples of how a child's peer group influences one's personality development. This is due to many factors, including the fact that people tend to be drawn to similar others – which cause children to be more drawn to peers than parents (as parents and children are rather unlike in many ways – height, social status, intelligence, etc.). For example, as children grow up, they continue to spend more time with their peers and less time with their parents. In addition, children of immigrant parents will learn the language of their social environment and speak with the accent of their peers as opposed to the accent of their parents. Also, peer rejection in childhood has been associated with maladjustment and poorer adult life status.

The Nurture Assumption also addresses other social psychological theories regarding potential influences of personality, including birth order, social comparison, and group socialization theory. Harris notes skepticism of birth order effects – the theory that one's chronological order of birth in relation to one's siblings (i.e., first-born, second-born, third-born, etc.) influences one's behavioral development. However, Harris cites several findings regarding how comparing oneself to peers, as well as one's role within his/her peer group, influences the development of personality and behavior.

Critics' Responses to the Book

Although *The Nurture Assumption* was lauded by many psychologists, it was also met with controversy. Many psychologists have criticized Harris for taking an extreme position on the nature-nurture topic with very limited data (Begley 1998), while other critics have argued that Harris overlooked some scientific findings that refute the theory that parents have very little influence over their children's personality development (Begley 1998; Kagan 1998). Some psychologists – such as Dr. Frank Farley of Temple University – have expressed concern over the idea that, after reading *The Nurture Assumption*, some parents may decide to neglect and mistreat their children

because they do not think it will have any effect on their children (Begley 1998).

Harris has addressed these criticisms in a foreword she wrote for the second edition of *The Nurture Assumption* (2009). She explained that there may have been some miscommunication between the message the book conveyed and the message that some readers received. This may have been due to having the scientific research cited in endnotes – making it less likely that readers would fully investigate the research she cited – or due to confusion regarding terms such as “peer group.” In regards to the concern over whether some parents may neglect or mistreat their children after reading her book, Harris points out that parents love their children not because they are required to. Most parents love their children because they want to; not because loving their children is the only way for the child to grow up to be a decent human being. “A good relationship is one in which each party cares about the other and derives happiness from making the other happy” (Harris 2006).

Conclusion

The key point of *The Nurture Assumption* focuses on the fact that, although children learn from their parents, they seem to learn more from their peers. As children continue to grow, they learn more from their peers and less from their parents, causing their personality development to be influenced more by their peers (and their genes) than their parents. The purpose of Harris’ book was to help decrease the anxiety that parents have when they fear they are harming the development of their children by not being perfect parents. Because children are influenced significantly more by their genes and their peers, Harris explains that her intent with *The Nurture Assumption* was to “make child-rearing a little easier, a little less stressful for parents. Alas, it has not happened, as far as I can tell.” (Harris 2009, p. xxii).

Definition

Clinicians define the state of being overweight or obese by body mass index (BMI), which is calculated by body mass in kilograms divided by the square of the person's height in meters. BMI from 18.5 to 25 is considered within a healthy range, or less likely to be associated with increased risk from certain weight-related diseases (González-Muniesa et al. 2017). The categories of underweight (BMI <18.5), overweight (BMI 25–30) to obese (BMI >30) are associated with increased risks of certain diseases, costs to reproductive performance, and life expectancy (GBD 2015 Obesity Collaborators et al. 2017; Global BMI Mortality Collaboration et al. 2016; Hammiche et al. 2012; van der Steeg et al. 2008; Zain and Norman 2008).

Introduction

Conservative estimates suggest that over one billion people worldwide are either overweight or obese (Wang and Speakman 2016). Obesity levels have more than doubled since the 1980s, with the estimate of overweight and obese adults climbing to ~38% of the global population (NCD-RisC 2016; Ng et al. 2014). Obesity is responsible for approximately three to four million deaths per year worldwide, predisposing suffers to a plethora of related diseases such as type 2 diabetes, cardiovascular diseases, metabolic syndrome, chronic inflammatory diseases, and 13 types of cancer (Buescher et al. 2013; González-Muniesa et al. 2017; Ng et al. 2014; Pearson-Stuttard et al. 2018; Whiteman et al. 2015; Wilson et al. 2018). Despite the costly implementation of public health policies, obesity levels continue to rise around the globe due to the complicated epidemiology and etiology of obesity (González-Muniesa et al. 2017). This entry concisely considers some of the possible evolutionary reasons why obesity has arisen, beginning with the evolution of our diet. Next, it will cover the evidence for the longstanding thrifty genotype hypothesis as a possible origin of obesity, and finally, consideration will be given to the role protein targets may play in the rise of obesity in humans.

The Evolution of Our Diet

The diet of an individual consists of many nutrients that are required in various proportions relative to other nutrients. These nutrients interact with each other and with the individual's life stage, genome, microbiota and condition. It is generally true that a single nutrient needs to be consumed at balance, and that over- or under-consumption is harmful to an individual's health (Raubenheimer et al. 2005). Therefore, in order to maximize fitness, an individual must balance ingestion and absorption of nutrients in appropriate proportions. Precisely which foods an organism ingests to achieve this balance is determined by how each nutrient affects appetite and satiety – which is specific to the evolutionary history of each organism (Simpson et al. 2004). The three major energy-contributing nutrients in any diet are carbohydrate, fat, and protein, also termed macronutrients. These macronutrients can explain a great deal of the physiological and behavioral variation between organisms and thus play an important role in determining evolutionary fitness (Raubenheimer and Simpson 2016).

Over the past ~40,000 years since the Paleolithic period, human diet has changed drastically, this change in diet has accelerated even further over the past ~50 years. Fossil studies of past humans show us they were limited for energy because sources of simple fats, starches, and sugars were much less abundant than they are today (Eaton et al. 1996), whereas complex sources of carbohydrate such as roots or tubers and sources of protein from fish or lean game meat were the main staples of a hunter-gatherer diet. Hunter-gatherer populations today, such as the Hadza, have very low levels of obesity (<5%) and rarely experience metabolic or cardiovascular diseases (Pontzer et al. 2018). Importantly, the Hadza people spend a lot longer engaging in physical activity than most of their Western counterparts, accumulating over 120 min each day (Pontzer et al. 2018). When many societies transitioned from a hunter-gather to agricultural lifestyle, diets increased in carbohydrate – mainly starchy grains. Although the shift to agriculture

occurred at differing times across societies, evidence from multiple regions indicate this rise in starch coincided with a reduction in protein. The agricultural revolution also produced an increased disease burden, due to closer living quarters, and increased the risks of famine due to reliance on crops (Prentice 2005; Wells 2012). Due to the availability of mass refining and improved transport of sugar and grains, the carbohydrate content in human diet increased further during the industrial revolution, although still at this time, obesity prevalence was low and considered a luxury of the wealthy (Simpson and Raubenheimer 2012).

In approximately the last 50 years, the macronutrient composition of our diet has changed even more, with most in developed nations having access to an abundance of food. We now have access to an unprecedented amount of simple sugars and fats, and highly processed foods are cheap and plentiful. In tandem with this nutritional shift, we are required to expend much less energy on subsistence activities than did our forebears (Simpson and Raubenheimer 2012). Despite this change in lifestyle, our physiology remains very similar to that of our ancestors. This led many researchers to hypothesize about evolutionary discordance, which suggests significant departures from our ancestral diet but not our ancestral physiology, have greatly contributed to noncommunicable diseases such as obesity (Konner and Eaton 2010). However, research investigating the interaction between our culture, genes, and environment (termed gene-culture coevolution) has shown recent positive selection for mutations such as lactose tolerance, that has arisen in societies that moved toward dairy farming for subsistence ~5000–10,000 years ago (Swallow 2003; Tishkoff et al. 2007). Moreover, the genes that confer some resistance to diabetes may well be under positive selection (Helgason et al. 2007) indicating that an adaptive lag between our genes and diet is not present for all nutritional changes in recent evolutionary history. Such evidence from gene-culture co-evolution studies may lend credence to another possible explanation for obesity: the thrifty gene hypothesis, because

these selection signatures are what one would expect to find under this hypothesis, and this is considered in the next section.

Thrifty Genes?

The thrifty gene hypothesis postulates that obesity may be the result of positive selection for genes that promote fat storage – these so-called thrifty genes may have come under selection during times of food scarcity in our evolutionary history (Gibson 2007; Wang and Speakman 2016). Now that most people in developed, and even many developing nations, have access to an abundance of food – these once thrifty genes – may now be maladaptive and thus lead to obesity. There are several reasons why this hypothesis is alluring to researchers. First, there is variation in obesity and related disease susceptibility in humans, and these traits are both genetically correlated and heritable (Gibson 2007). Second, when we look into our own evolutionary past, we can see shifts in diet, beginning with an energy limited environment changing to an energy abundant one (Simpson and Raubenheimer 2012). Third, when we put humans in context with other extant primates, we see many have an annual body mass cycle where they consume in caloric excess when fruit is abundant and experience the lean season when fruit is more scarce (Irwin et al. 2015). In fact, this type of endogenous cycle where animals eat to a positive energy balance in preparation for energy scarcity is found in other taxa such as barnacle geese, ground squirrels, alpine marmots, bears, and hairy-nosed wombats (Atkinson et al. 1996; Finlayson et al. 2010; John 2005; Körtner and Heldmaier 1995; Portugal et al. 2007). It may appear plausible then that humans are perhaps accumulating weight for a winter that will never come.

However, studies that have investigated positive selection in alleles that may confer a fitness advantage to efficient fat storage have failed to demonstrate any selection signature that would be congruent with the thrifty genotype hypothesis (Ayub et al. 2014; Wang and Speakman

2016). Additionally, there are several other limitations to this hypothesis; they all relate to famine as a selective pressure. It seems that while Paleolithic people were in an energy scarce environment (comparative to now), famines were more likely during the agricultural and industrial revolutions. To confer a great enough selective pressure, famines would likely need to be quite frequent and quite devastating – the mortality rate from the famine would need to be high enough to exert sufficient selective pressure (Gibson 2007; Speakman 2006). There is much debate in the literature about the frequency and severity of famines throughout the past ~50,000 years; some researchers define famines occurring as frequently as every decade, others as only once every century, all with differing mortality rates. This makes determining whether famine is a sufficiently strong and regular selective pressure difficult (Prentice 2005; Speakman 2006). It is also more likely during these times of scarcity that people died from infectious diseases, rather than starvation itself, although interestingly a BMI >30 is associated with an increased chance of survival from some infections such as community-acquired bacterial pneumonia (Corrales-Medina et al. 2011). It is possible therefore that the value of the thrifty gene confers different advantages to those previously investigated, although a BMI >30 is also associated with an increased risk of mortality from other acute infections (Dhurandhar et al. 2015). Nevertheless, little direct evidence exists for the thrifty genotype hypothesis.

Are We Eating to a Protein Target?

Rather than thrifty genotypes, perhaps the more recent changes in our diet have led to obesity, because many organisms, including humans, are eating to specific nutrient targets (Raubenheimer and Simpson 2016). Organisms possess nutrient-specific appetites that maintain homeostasis and alter the consumption of different nutrients (Corrales-Carvajal et al. 2016). If the correct proportion of nutrients required for maintaining

health is not available however, organisms attempt to remedy this by ingesting a range of foods with differing but complementary nutrients (Raubenheimer and Simpson 1997; Waldbauer and Friedman 1991).

Much data across taxa, (including primates, flies, and murids) indicates that protein is the primary determinant of appetite and satiety (Felton et al. 2009; Gosby et al. 2011, 2014; Lee et al. 2008; Simpson et al. 2004; Solon-Biet et al. 2014; Sørensen et al. 2008). Therefore, generally food is ingested in a manner that ensures protein consumption is within a strict range of values, but a wider range of carbohydrate and lipid intake can be tolerated. This may be because protein overconsumption can carry physiological and metabolic costs associated with excretion, whereas underconsumption leads to a decrease or cessation in reproductive output (Piper et al. 2005; Solon-Biet et al. 2015). If excess carbohydrate or fat is consumed however, energy stored as body fat can serve as an important buffer against seasonal variations in energy supply (Prentice 2005; Walker et al. 2017).

Because protein consumption is so closely linked to satiety, it has the capacity to shape feeding behavior, and can be exploited to facilitate the loss of body fat by curtailing appetite through consumption of high protein diets. By contrast, consuming low protein foods to meet a protein intake target can result in overconsumption of sugar and fat, which in the long term can lead to obesity (Gosby et al. 2014; Raubenheimer et al. 2005). Together, this has led to the hypothesis that the current obesity epidemic is fuelled (at least in part) by the unprecedented abundance of low protein, energy dense foods that are highly palatable, yet have little satiety value (Martínez Steele et al. 2018; Raubenheimer et al. 2005).

Direct evidence suggesting that humans are eating to reach a protein target comes from an experiment where participants volunteered to stay in a chalet in the Swiss Alps. They stayed in the chalet for 6 days in total, during the first 2 days they were free to select their own food for each meal from a buffet, which varied in macronutrient proportions. The experimenters were

interested only in protein consumption relative to fat plus carbohydrate consumption. For the next 2 days, participants were split into groups, one group received higher protein food (but lower fat and carbohydrate) than they had self-selected in days 1 and 2, and the other group lower protein (but higher in fat and carbohydrate), food than they had self-selected in days 1 and 2. The high and low protein food was designed to seem identical to the participants. For the final 2 days of the experiment, all participants ate as they chose – the same as on days 1 and 2 of the experiment. The results showed that participants ate to a protein target at the expense of carbohydrate and fat, thus, those put on a higher protein diet (than they self-selected in days 1 and 2) on days 3 and 4 underconsumed carbohydrate and fat, whereas the group on the lower protein overconsumed carbohydrate and fat in an attempt to consume more protein. The researchers concluded that when humans are forced to make choices about food, protein intake is prioritized over carbohydrate and fat (Simpson et al. 2003). This is consistent with many other species studied, including other primates, murids, fruit flies and Mormon crickets, suggesting that leveraging protein intake over carbohydrate and fat is evolutionarily conserved (Gosby et al. 2014; Simpson et al. 2003; Simpson and Raubenheimer 2012).

Conclusion

The origins and increased prevalence of obesity are multifaceted, and evolutionary explanations are paramount to understanding the obesity epidemic. The rapid change in our diet in recent years, as well as a shift to a more sedentary lifestyle, interacts with our nutritional balancing act to attempt to eat optimal quantities of protein, which perhaps leads to overconsumption of carbohydrate and fats. Although an overabundance of highly processed sugar and fat dense foods undoubtedly plays a role, the rise in the prevalence of obesity is unlikely to be caused by positive selection for a thriftier genotype.

[Continuity](#); [Identity](#); [Persistence](#); [Recognition](#); [Selfhood](#); [Time](#)

Definition

The apparent maintenance of object identity over time, especially during periods of non-observation.

Introduction

Typically-developing human beings and at least some other animals tend to regard the objects around them, including other organisms, landscape features, and artifacts, as maintaining their identities – remaining the “same thing” – over time whether they are observed continuously or not. Objects are, in other words, regarded as “permanent” or “persistent” by default. Both experimental and theoretical practice in psychology largely adopt the “naïve realist” assumption that objects having the properties they are typically perceived to have are ontologically real, i.e., they in fact exist in an observation-independent way and in fact maintain their identities over time. Given this assumption, object permanence is the recognition or understanding of the continuous, identity-preserving existence of objects (see Hoffman et al. (2015) for a critique of naïve realism). As object permanence must in any case be inferred from sensory input and memory, the ontological question of whether objects are in fact permanent can be set aside, in practice, in favor of the more properly psychological questions of how object permanence is inferred, how the ability to infer object permanence develops, and how and why an ability to infer object permanence evolved within animal lineages exhibiting complex cognition. It bears emphasis that “inferences” of object permanence are typically, but not always (e.g., Eichenbaum et al. 2007), automatic: subjects typically “perceive sameness” instead of having to consciously infer it.

Short- Versus Long-Term Object Permanence

The conditions under which human infants, children, and adults infer object permanence during

short (seconds) visual displays have been intensively studied, primarily using visual occluded-motion paradigms (reviewed by Flombaum et al. 2008; Fields 2011). Infants infer trajectory continuity and hence object permanence for a specific range of trajectory shapes and occlusion times beginning at about 3 months old; by 2 years old, infants employ essentially the same trajectory-shape and occlusion-time criteria used by adults. Smooth trajectories and relatively short occlusion times robustly indicate object sameness and hence object permanence; apparent “absorption” of an object by an occluder followed by “emission” of a visually indistinguishable object from the occluder after a long delay or from a position unreachable by a smooth trajectory suggests non-sameness and hence a violation of object permanence. Trajectory-based object permanence is impervious to a wide range of feature changes, e.g., of size, shape, or color of the moving object, in both infants and adults.

While philosophical conundrums such as the “Ship of Theseus” have been discussed since the pre-Socratic period, the inference of object permanence over longer periods – tens of seconds to decades – of non-observation has received relatively little direct experimental investigation. On the shorter end of this temporal range (tens of seconds to minutes), numerous studies have demonstrated that infants are surprised, as adults are, by object permanence violations as early as 2.5 months old (reviewed by Baillargeon 2008). For example, surprise is elicited when an object is placed behind an opaque screen, which after a short delay is lifted to reveal that the object is no longer there. As the period of non-observation increases, however, experimental manipulations become progressively more difficult, and studies tend to be framed in terms of “object recognition” instead of “object permanence.” Object recognition in the sense used here requires object permanence; i.e., it requires an inference of continuing object identity. If for any reason object permanence cannot be inferred, the perceived object is “seen” not as the same thing observed before but rather as novel. Such failures of recognition occur, for example, in severe anterograde amnesia, e.g., Korsakoff syndrome (reviewed by Fama et al.

2012), demonstrating that short-term object permanence may be preserved but long-term object permanence lost. The relative contributions of semantic memory, episodic memory, and causal reasoning to object recognition following moderate to long periods of non-observation (hours to decades) remain to be determined and may vary widely with object type and context (reviewed by Eichenbaum et al. 2007; Scholl 2007; Fields 2012).

Insight into the difficulty of characterizing object permanence inferences across longer gaps in observation comes from fundamental computer science. Recognizing complex objects requires mereological (part-whole) reasoning. In most situations, mereological relations cannot be defined precisely; they are only “rough” or heuristic (Dütsch and Gediga 2000). At low levels of granularity, “parts” become generic and indiscernible, rendering highly similar assemblages effectively indiscernible. At higher levels of granularity, parts may change their properties over time and hence require part-level judgments of “sameness.” In this setting, additional information, e.g., causal or historical information, must be added to track individual object identity. Such information is strictly unavailable during periods of non-observation, so object identity becomes both hypothetical and dependent on the choice of heuristics, e.g., the choice of features or causal constraints to regard as “essential” for maintaining object identity.

The tools and techniques of developmental robotics (reviewed by Baldassarre and Mirolli 2013; Cangelosi and Schlesinger 2015) provide new empirical approaches to object permanence. These range from replicating classic experimental paradigms such as occluded motion using fully specified visual-processing and inference architectures to investigations of self-motivated environmental exploration, multiple object tracking, sensory-motor coordination, and language learning. Such studies make explicit not only the memory resources and inferences needed to establish object permanence but also the role of assumed or inferred object permanence as an enabler of complex cognition and behavior.

Is Object Permanence Innate?

The essential role of object permanence in human cognition has long led to it being considered innate (Baillargeon 2008). In functional terms, object permanence being innate means that the human neurocognitive system already has the organization needed to express behavioral responses indicating an inference of object permanence at or soon after birth. Recently developed protocols for functional imaging of neonates, including preterm neonates, allow the functional connectivity of the long-range networks implementing inferences of visual object permanence (e.g., the visuo-motor, categorization, and salience networks) to be tracked in parallel with emerging infant abilities (e.g., Ball et al. 2014; Gao et al. 2015).

While systematic pathological disruption of object permanence in infants has not been demonstrated, considerable evidence indicates that the perceptual processing pathways that implement object permanence are affected in autism spectrum disorders (reviewed by Gomot and Wicker 2012; Fields and Glazebrook 2017). Hundreds of genes, many of them known to act prenatally to influence neural growth and connectivity, have been associated with autism (reviewed by Geschwind and Flint 2015); these potentially provide a molecular avenue for investigating the emergence of object permanence both developmentally and evolutionarily.

A Special Case: The Self

A particular instance of object permanence is crucial for development of a coherent psychology: the experienced self and its associated body. The experienced self is fixed as a reference point for other objects and object-directed actions early in infancy and may be innate (reviewed by Rochat 2012). How the experienced self is to be defined conceptually, how it is implemented, and how it is updated to track physical and psychological changes remain significant open questions (e.g., Metzinger 2011; Klein 2014). Evidence that the default-mode network, which is implicated in

representation of the self (reviewed by Buckner et al. 2008), is already largely functional in early infancy (Gao et al. 2015) may shed light on the development and assignment of permanence to the experienced self.

Object Permanence and Time

The idea that an object can change its state cannot be formulated without an assumption of object permanence. Conversely, the idea of object permanence cannot be formulated without a sense of time and hence at least one object – a clock – that changes state. An internal not necessarily conscious sense of duration sufficient at least to distinguish “now” from “then” is, therefore, required for object permanence. The human implementation of such an internal “clock” is beginning to be mapped out (reviewed by Merchant et al. 2013; Mathews and Meck 2014); however, a mechanistic connection between time perception and object permanence has yet to be made.

Phylogenetic Distribution and Evolutionary History

Food caching, wayfinding, tool construction and use, long-term pair bonding, and negotiated social relations all require recognizing an object or a location as “the same” after a period of non-perception and hence suggest object permanence. Comparative studies of object permanence have, accordingly, focused on birds (many species, reviewed by Güntürkün and Bugnyar 2016), social carnivores (primarily domestic dogs, reviewed by Zentall and Pattison 2016), cetaceans (primarily dolphins, e.g., Johnson et al. 2015), and great apes (all species, e.g., Karg et al. 2014). The experimental tasks employed typically replicate in a species-appropriate way those used with human infants or children. While both experimental designs (e.g., Jaakkola 2014) and inferences from small sample sizes (e.g., Thornton and Lukas 2012) in this literature have been criticized, there is broad consensus that animals exhibiting complex cognition rely on object permanence.

The deep divergence between birds and mammals (approx. 300 million years; Güntürkün and Bugnyar 2016) indicates either a deep evolutionary origin of object permanence or significant convergent evolution. The question of whether object recognition and wayfinding abilities in rodents, reptiles, or even social insects can be regarded as evolutionary precursors or rudimentary forms of object permanence therefore bears consideration. Conclusive demonstration of a lack of object permanence, e.g., conclusive demonstration of a systematic inability to recognize “the same individual” after some period of non-observation, in a mammalian system would also be valuable in clarifying the evolutionary history of this capability.

Object Permanence and the Social Brain

The Social Brain hypothesis is a pillar of human evolutionary psychology (reviewed by Dunbar and Shultz 2007; Adolphs 2009). The complex social relations envisioned as the primary drivers of human cognitive, emotional, and behavioral evolution within the Social Brain framework inevitably involve abilities to reliably identify particular individual humans over long periods of time and hence moderate to long periods of non-observation. Such abilities require an inference of continuing existence with individual identity maintenance; hence they require object permanence.

Evolutionary Developmental Perspective

Object permanence allows infants and children to exchange fitness-enhancing attachment signals with their mothers, other family members, and nonfamily caregivers. It can, therefore, be regarded as an ontogenetic adaptation (Bjorklund and Pellegrini 2002). It continues, however, to enable qualitatively new capabilities across the lifespan, e.g., the ability to regard abstracta such as religions or social organizations as maintaining their identities over time. As the

selective pressures acting on these later-developing abilities may be different from those acting during infancy or childhood, the robust childhood expansion of object permanence capabilities away from family members to “objects” in general may be regarded as a deferred adaptation.

From a mechanistic perspective, the relevant questions are how the mechanisms enabling object permanence in infancy develop pre- and perinatally, how they later expand as the infant and then the child interacts with her environment, and how this extended developmental system evolved within the animal and particularly primate lineage. The direct mechanistic coupling of evolution and development characteristic of “evo-devo” biology (reviewed by Müller 2007; Carroll 2008) has yet to be achieved within psychology. The centrality of object permanence to complex cognition, together with its broad phylogenetic distribution, suggests that it is an ideal test case for such an endeavor. A deep understanding of how the pre- and postnatal developmental mechanisms that support object permanence have evolved in both avian and mammalian lineages may provide new insights into the generation of novel cognitive and emotional variants and the selective pressures that act on them over evolutionary time scales.

Conclusion

With every new demonstration of quantum superposition or entanglement at macroscopic scales (e.g., Wiseman 2015), the likelihood that observation-independent, time-persistent objects can even be defined at the level of fundamental physics decreases. If the objects of human perception cannot be defined within physics, an understanding of what they are and what it means for them to maintain their individual identities over time must be developed within psychology. Hoffman et al. (2015) have suggested that “objects” are in fact bundles of organism-specific fitness consequences. If this is the case, object permanence is the inference that fitness consequences that are correlated at one time will remain correlated at subsequent times. Sophisticated

neurocognitive mechanisms are required to make such inferences. Developmental robotics, functional neuroimaging of infants, and evolutionary developmental psychology provide new conceptual and empirical tools that can be combined with the traditional methods of experimental psychology to identify these mechanisms and to characterize their development and evolution.

Definition

Object play involves playful activities with toys or other objects, instead of social or interactive play with peers.

Introduction

Play is certainly an important component in the course of children's development; in fact, it takes up an appreciable portion of their time budgets, considering that all children engage into play activities throughout their childhood. Many definitions have been put forward in an attempt to define what play is and of the different types of play available in the literature. Some have had more examination than others. For example, there is a great amount of literature on children's pretend play, while research on rough-and-tumble play is lacking (Smith et al. 2015). In this entry, we will consider the evolutionary biological perspective on play development, we will address what playful behavior entails, and finally, we will focus on object play and tool use during the periods of infancy and childhood.

An Evolutionary Perspective

According to evolutionary biology, the desire to play in specific ways and at specific points in life is shared among a variety of mammals (LaFreniere 2011). Evolutionary biologists have long been intrigued to the origins and functions of play due to its complexity as a phenomenon in young mammals (LaFreniere 2011), not only to observe but also to define it (Pellegrini and Smith 1998). In the evolutionary biology dictionary, the term “functions” with regard to play refers to when a behavior has typically added to the survival or reproductive success of an individual (genes) over many succeeding generations (Pellegrini and Smith 1998b). Functions can also be defined in the context of beneficial outcomes during the life cycle of the individual player (Pellegrini and Smith 1998b).

Evolutionary biologists interested mainly in the study of animal behavior (hereafter ethologists) generally consider play as having been acquired by our species through the process of natural selection, in order to provide deferred benefits to the individual (LaFreniere 2011). In other words, through play a child develops and practices skills crucial to survival and reproduction in adulthood (Smith 2009). Yet, play may also produce immediate benefits to the young individual, and modern ethologists acknowledge that natural selection acts throughout life cycle, a view now called *life history theory* (LaFreniere 2011).

Life history theory is a worldwide accepted analytical framework, used mainly in biology and evolutionary psychology since the 1970s (LaFreniere 2011). It considers an organism as an ever-changing life cycle – not as a static adult – suggesting that certain species-typical characteristics evolve to favor somatic and reproductive efforts throughout life span (LaFreniere 2011). Accordingly, Bogin (1999) postulated that because of a finite amount of time, energy, and resources available, individuals must make choices regarding their behavioral priorities and allocation of resources with respect to developmental periods and life goals suitable to those periods. For example, despite its clear costs, during the early juvenile period, play is prioritized in all social primates, while social play takes up most of the time not spent eating and sleeping (LaFreniere 2011). This fact is considered to be crucial as the main basis for concluding an adaptive function of play, because natural selection favors only behaviors whose benefits clearly outweigh the associated costs (LaFreniere 2011). Play can be costly in terms of time and energy devoted to it as it diminishes the time, effort, and energy spent on other activities.

Despite such costs, there is a natural tendency of young mammals to engage in play as long as and as often as ecological constraints and opportunities afford (LaFreniere 2011); it is in fact indispensable to the development and good functioning of a healthy adult.

Characteristics of Playful Behavior

Although many researchers have attempted to define what we call “playful behavior,” this is not an easy task. Animal ethologist Robert Fagen (1974) proposed two approaches, which can be used to define play: the functional approach and the structural approach. The functional approach suggests that play does not have a clear external goal or an obvious end in itself neither clear immediate benefits to the individual (Smith et al. 2015). In fact, a “functional” way of perceiving play is suggested – play is performed rather for its own sake and for enjoyment instead of for any other external purpose (Smith et al. 2015). Therefore, if an external goal exists such as a need to seek comfort or attention, then the behavior cannot be considered as play (Smith et al. 2015). However, it is important to highlight that, although playful behaviors do not generate any clear immediate benefits for the youth, many theorists do believe that children indeed benefited from playing; there is an ongoing controversy as to what the benefits of play exactly are (Smith et al. 2015).

The structural approach is primarily concerned with behaviors present only during play or the way these behaviors are organized during playful activities (Smith et al. 2015). These behaviors are usually called “play signals” and could, for example, take the form of laughter or the “open-mouth play face” which both signal play (Smith et al. 2015). However, it is arguable that not all play is characterized by play signals. In fact, the structural approach goes a step further and suggests that for behaviors to be considered as playful, they need to be “repeated,” “fragmented,” “exaggerated,” or “reordered” (Smith et al. 2015). Thus, if a child is just running up a slope may not be playing, but if he or she runs up and slides down the slope several times which indicates repetition, runs just halfway up which shows fragmentation, takes unusually large or small steps or jumps which suggests exaggeration, or crawls up and then runs down which indicates reordering, then we could possibly agree that this behavior is playful (Smith et al. 2015).

The two approaches, although logically different, could be considered to be theoretically in parallel and complementary to each other; after all, the child running up and down the slope has no clear, immediate goal except from enjoyment (Smith et al. 2015).

Finally, another approach suggests that play or playful behavior can be identified through a number of different criteria but always in conjunction with the two previous approaches (Smith et al. 2015). No criterion is adequate enough to define playful behavior, but the more criteria are present, the higher the agreement will be on that a behavior is play (Smith et al. 2015). Based on this premise, Krasnor and Pepler (1980) proposed a model, which suggests that playful behaviors are characterized by a form of “flexibility,” “positive affect,” “nonliterality,” and “intrinsic motivation.” Flexibility refers to the form and content of play where objects are being put in different combinations and roles are being performed in new ways – these are the structural characteristics of play (Smith and Pellegrini 2013). Positive affect refers to visible signs of enjoyment such as when children smile and laugh during their time while playing (Smith and Pellegrini 2013). Nonliterality deals with elements of “pretend” during play (Krasnor and Pepler 1980) such as acting out hypothetical scenarios. Lastly, intrinsic motivation refers to the fact that such behaviors are conducted for their own sake with participants being mostly interested with the behaviors themselves (i.e., “means”) rather than the action (i.e., “ends”) of the behavior (the process is more important than any goal) (Pellegrini et al. 2007).

The play criterion approach does not aim to produce an unequivocal definition of playful behavior. It does, however, identify a continuum of play, that is, from nonplayful to playful behavior, as well as how different theorists agree on what to call playful behavior (Smith et al. 2015). As it has been discussed so far, the main “play” criteria for young children are flexibility, enjoyment, pretense, and no specific goal while doing so.

Play and Exploration

The play criteria, as discussed above, distinguish “play” from “exploration.” Play and exploration were often classified together in earlier writings perhaps because both of them were not goal-directed neither guided through reinforcement (Smith et al. 2015). Yet, it is also true that for young infants, during the sensorimotor stage of their development (see ► [Sensorimotor Play](#)), the difference between exploration and play is harder to make, as, for very young children, all objects are unusual (Smith et al. 2015). Once children enter their preschool years, however, the difference is easier to make (Smith et al. 2015). This was illustrated by an experiment conducted by Corinne Hutt (1966) by creating a unique toy – specifically a box where children could sit on, with a lever that could make the sound of a buzzer. Young children around the age of 3–5 years were rather thoughtful when the novel toy was introduced to them by touching it, by feeling it, and by trying out the lever – they were in fact trying to figure out what the novel object could do or in other words “exploring.” Soon after, this changed as the child would regularly relax and sit on the object performing frequently with the lever – perceived as more playful behavior. Based on these observations, Hutt proposed that children typically continue from thorough exploration of different objects to more playful activities.

In addition, exploration in relation to play is characterized by fast heart rate, reduced distractibility, and flat affect (Pellegrini 2016). On the other hand, when playful behavior occurs, there is low heart rate, children are more relaxed, high level of distractibility, and positive affect (Hutt 1966). Exploration was identified as relatively thoughtful and paying attention to details, typically asking, “what does this object do?” – while play was characterized by a variety of behaviors typically asking, “what can I do with this object?” as well as being relaxed while using the object.

Further, exploration usually predates different forms of object use and play in human animals (Belsky and Most 1981). Influential work from

Belsky and Most (1981) showed that toy exploration was the main activity of children aged 7.5–10.5 months, with no signs of playful behavior, while from around 9 to 10.5 months of age, they identified objects as they manipulated them. At 12 months, object play became into view, along with exploration and naming of objects. Indeed, all types of play follow exploration – animal behaviorists suggest that children’s play does not only involve objects but rather ranges also along social and locomotor dimensions (Burghardt 2005). The latter two are being more closely interrelated; for example, play-fighting or rough-and-tumble play has both social and physical dimensions (Pellegrini and Smith 1998a). Most child developmental research, however, has mainly focused on object play dimensions (Smith et al. 2015).

Play with Objects

Jean Piaget’s (1952) theory of cognitive development suggests that young children’s perception and understanding of the surrounding world depend on their motor development – a fundamental skill necessary for the young child to associate visual, tactile, and motor representations of objects. Specifically, the infant has to understand that objects exist even when they cannot be seen, touched, heard, or sensed in any other way – what we call “object permanence” – and this understanding comes through touching and handling objects in different ways (Siegler et al. 2017). Piaget gave a comprehensive description of the varied ways in which children make use of and manipulate objects, including play (Smith et al. 2015). Although initially this is best expressed as exploratory, as the child progresses through the sensorimotor stage, which usually lasts from birth until 2 years of age, exploratory behaviors are repeated and thus perhaps enjoyed – two criteria for playful behavior to be present (Smith et al. 2015). These behaviors become also more flexible, such as that some of them would easily be characterized as playful (Smith et al. 2015). Piaget

suggested that this behavior could also be called “practice play,” in terms of manipulating and bumping objects together and laughing (Smith et al. 2015).

As Piaget’s theory suggests, young children during their first 2 years of life are primarily focused on the activities of their own body (Siegler et al. 2017). Once their attention shifts from basic body reflexes to the events of the surrounding world, the stage is set for the appearance of object play (Hughes 2010). Except from the infant’s interest in the world around them, however, there is another requirement for object play to occur; the motor skills are needed to allow the infant to grasp and handle play objects (Hughes 2010). As mentioned above, Piaget suggested that during the first 2 years of life, children develop their motor skills, and this is when children start engaging into play with objects.

Object play refers to playful behavior involving the use of different objects such as building blocks, jigsaw puzzles, cars, dolls, etc. (Smith and Pellegrini 2013). For instance, when babies engage in play with objects, they usually mouth objects and then they drop them down, while toddlers manipulate the objects such as assembling blocks, or sometimes they pretend play such as feeding a doll (Smith and Pellegrini 2013). In fact, when children are pretending using objects, at first, they imitate someone else’s use of those objects (Pellegrini 2016). Over time, young individuals learn how to use other more abstract objects to portray other objects (Pellegrini 2016). Accordingly, object play is also evident when children use objects in varied ways (Pellegrini and Hou 2011) such as using a pencil to represent a hammer. Play with objects gives the opportunity to children to create new combinations of actions as well as to advance their problem-solving skills (Smith and Pellegrini 2013). Indeed, of all the possible uses of objects, play with objects is most highly akin to creativity (Pellegrini and Hou 2011).

In modern societies, object play typically involves toys which are made to favor children’s

play by being created based on mass media prototypes (Smith 2009). There is a huge production not only of simple toys and objects such as building blocks, jigsaw puzzles, cars, dolls, and toy animals but also of toys used for pretending and fantasy activities, such as farm sets, castles, trains, action figures, and action objects based on either older but ongoing or current TV series or films such as Star Wars (Smith 2009).

As mentioned earlier, before babies, toddlers, and children engage in object play, they must explore the object first (Hutt 1966). In this initial exploration, young individuals extract characteristics of and uses for novel objects, and individuals then use this information as a basis for play bouts (Pellegrini et al. 2007). To illustrate, imagine a child entering the nursery school for the first time, being introduced to a completely new setting (Pellegrini et al. 2007). The child will allow substantial amount of time during the very first few weeks of their experience, to explore the physical and social environment of the nursery school – being a passive onlooker (Pellegrini and Goldsmith 2003). Exploration is used not only to become familiar with a new setting, but it is also needed to identify any potentially dangerous aspects of an environment and discover how to stay away from them (Spinka et al. 2001). Once a child determines that the novel environment is safe, then play can occur (Pellegrini and Goldsmith 2003).

In addition, establishing an accurate time frame for object play during childhood is challenging, considering that object play is usually conflated with other forms of object use (Pellegrini 2016). In a study by Belsky and Most (1981) where object play was clearly differentiated from other forms of object use, they concluded that it begins around 1 year. Further studies concluded that by 3–5 years of age in American and UK preschool settings, object play increases and then declines (McGrew 1972; Pellegrini and Gustafson 2005; Pellegrini and Hou 2011).

Object play becomes increasingly social as the child grows (Rubin et al. 1983). To illustrate, they concluded that less than 2% of preschool and kindergarten children's play is solitary, while 12% and 28% of preschoolers and

kindergarteners, respectively, is social (Rubin et al. 1983). Therefore, not only does object play expand throughout childhood, but it also becomes progressively social. Finally, it should be noted that any benefits of object play should be compared against those of instruction, keeping in mind different external influences such as the age of the child, the type of task, and whether learning is for particular skills or a more general developmental acquirement (Smith and Pellegrini 2013).

Gender Differences in Object Play

Evidence about gender differences in object play as well as in the overall frequency of object play between young boys and girls during the sensorimotor period is lacking (Belsky and Most 1981). However, studies have suggested that the nature and choice of toys do vary, especially after the sensorimotor stage. For instance, Smith and Daglish (1977) found that at 1 and 2 years of age, boys engage more into active play and forbidden play such as playing with wall sockets, pulling curtains, or climbing on furniture and used more transportation toys. Girls, on the other hand, engaged more into play with dolls and soft toys. These kinds of conclusions are also illustrated in other studies with children aged 2, 3, or 4 years, both at home settings and in nursery classes; boys tend to prefer activities such as throwing or kicking balls along with transportation toys, while girls tend to prefer dolls and dressing up (Smith 2009).

Tool Use

According to Bruner (1972), the design features that object play entails make it an appropriate and suitable way of developing tool-using skills. Object play, although highly enjoyable in itself and intrinsically motivated, offers repetition in the practice of a range of relevant skills (Smith 2009).

When considering the early development of tool use in infancy and childhood, the extent to

which young children can indeed explore different objects' functions should be kept in mind (Deák 2014). Ideally, a common definition of "tool use" suggests that individuals make use of objects not attached to the environment or being part of individuals' bodies, in the service of a goal, for example, getting food (Shumaker et al. 2011). To illustrate, using a fingernail to twist a screw would not be considered as an example of tool use but using a screwdriver would (Pellegrini 2016). Tool use is an activity that encourages children's learning on how to use tools according to cultural conventions, such as using a fork (Pellegrini 2016). As mentioned above, using tools appears relatively early in human ontogeny, with an increasing progression in terms of skills from infancy to childhood (Cutting et al. 2011).

Object functions depend on the physical layout and properties of objects such as their material, part configuration, and markings (Deák 2014). These object properties are related to tool use, and this is explained through the concept of *affordances* as suggested by Gibson (1982). An affordance is the extent to which an organism can interact with an object based on the object's properties (Gibson 1982). For example, to humans a cup affords containment of liquids or solids smaller than the mouth of the cup such as flour as well as tracing circles on paper (Deák 2014). Here, it is important to mention that affordances are inherent to the object-organism interaction rather than to the object alone, as they are characterized by a distinct organism's potential for interacting with those properties (Deák 2014). Individual humans can achieve different affordances from the same object too of course such as a skilled player can exploit more affordances on a guitar when compared to an inexperienced person. This concept is relevant when we examine the early development of tool use, because in reality most objects or tools are designed to afford actions of adults and not of infants and young children (Deák 2014). As a result, infants must learn how to use tools and objects in a world with a setup engineered for adults (Deák 2014).

Unfortunately, infants and young children are not frequently or sometimes not at all allowed to

explore object affordances or in other words to explore what they can do with a particular object. This is not only because of young children's physical limitations but also by the limited accessibility to these objects as adults usually design children's environments in such a way that they prohibit children's access (Deák 2014).

However, as infants grow and develop so do their sensory and motor abilities, and these are the necessary skills needed for the development of tool use. Infants aged 6–12 months old readily manipulate novel objects in order to explore their functions and properties – squeezing soft objects or banging hard objects (Bourgeois et al. 2005). As explained above, it is through exploration that children become familiar with novel objects, and once they do so, they enjoy their interaction with them. Exploration is a progressive, embodied, multimodal process that progressively allows children to adapt their reaching and refine their abilities to specific and similar novel objects, in other words, to detect new affordances (Deák 2014). Refinement can be gradual in the sense that younger infants learn how to use a type of tool, for example, a spoon, after a substantial amount of time of experience. Consequently, it has been suggested that tool-using skill depends on infants' and young children's experiences with objects (Deák 2014). The reason why tool use learning is protracted is partly because young children need time also to consolidate their newly acquired sensory and motor skills.

Further, as Tomasello (1999) suggested, tool use is supported by social interaction, with adults having an important role in children's tool use learning. Specifically, infants and young children shift their attention to objects as a consequence of interaction or observation of adults using objects and tools (Deák 2014). For instance, when adults hold objects, children in turn become interested in those objects and reach out for them, to examine and learn about them (Tomasello 1999). Thus, it is suggested that social learning and sensorimotor development are combined in an attempt to favor tool use learning in infants and young children.

In summary, as the young child moves from infancy to childhood, their tool use skills

depended on active, sensorimotor development. Through the acquisition of their sensory and motor abilities, infants and young children are able to explore novel objects and gradually learn how to use them in different ways, just like adults.

Conclusion

This chapter has presented a short introduction about the evolutionary biological basis of “play development” as studied among a variety of mammals. As it has been suggested, it is through play that children develop and practice skills crucial to survival and reproduction in adulthood. While play can be costly in terms of time and energy devoted to it as it diminishes the time, effort and energy spent on other activities, there is a natural tendency of young mammals to prioritize and engage in play activities during the early-juvenile period. Importantly, play allows the young individual, after they have determined that a novel environment is safe, to generate play behaviors and explore different object functions they can afford performing in terms of their age and current skills. Overall, research suggests that play is indispensable to the development and good functioning of a healthy adult while it is through the acquisition of their sensory and motor abilities that young children can develop their tool-use skills and learn how to use novel objects in different ways.

Synonyms

Absolutism; Moral realism; Objectivism

Definition

Objectivity – the quality of existing independently of a subject's beliefs or desires. Not dependent for its properties on any person's subjective

experience. Typically discoverable by publicly available and evaluable means.

Introduction

For purposes of this entry, a domain of facts is objective if those facts both (a) *exist* and (b) are *mind-independent*, meaning they do not depend for their existence on any human beliefs, attitudes, or desires (though for simplification, this article will only refer to beliefs in what follows). Accordingly, moral facts are objective just insofar as they both exist and are mind-independent. Here, the focus will be on how evolutionary considerations bear on the objectivity of morality. This article will not consider other ways in which evolutionary considerations bear on other moral phenomena, including how they might have shaped core moral emotions such as compassion or shame or widespread moral practices such as reciprocity and punishment.

For many philosophers, the objectivity of morality constitutes a “fundamental commitment” (Wong 2014, p. 337); the objective demands of morality are “nonnegotiable” (Joyce 2006, p. 117). Psychologists also discuss morality in objectivist terms, drawing clear distinctions between social or conventional norms on the one hand and moral norms on the other. According to one influential account, moral norms are distinguished in being universalizable and, more importantly, applicable independent of any authority or sanction (Turiel 1983).

Additionally, nearly all philosophers and psychologists also maintain that ordinary folk are committed to objectivism about morality, such that if two people disagree about the moral status of a moral claim – say, whether or not discriminating against someone on the basis of their sexual orientation is morally permissible – at most one of them can be correct (e.g., Smith 1994; Shafer-Landau 2003). The “philosopher's task,” according to one prominent account, is to make sense of precisely the puzzling objectivity of morality (Smith 1994). Philosophers predominantly base their claims by canvassing the nature of moral language and debate, by examining ordinary intuitions about the moral domain, and by

reflecting on the phenomenology or felt experience of moral life (Gill 2009). Psychologists, by contrast, have tested this claim using experimental methods, with several studies showing that individuals do, in fact, show objectivist tendencies (for a review, see Sarkissian 2016).

Evolutionary Arguments and Skepticism About Objectivity

Recently, some researchers have suggested that evolutionary theory can pose a serious threat to the purported objectivity of morality. Specifically, it can undermine the notion that most commonsense and widespread moral beliefs are justified by referring to mind-independent moral facts. Evolutionary explanations of commonsense moral beliefs do not, in themselves, lead us to deny or rule out the existence of mind-independent moral facts. Indeed, this is not the general strategy of such “debunking” explanations (Nichols 2014). Instead, evolutionary explanations are thought to undermine the warrant or justification of these beliefs. They can do so in several ways. Such explanations can provide a complete or convincing account of the causal processes giving rise to the belief in question without, at any point, having to say anything at all concerning whether or not that belief tracks any facts or truths about the world (Joyce 2006). Or, such explanations can show that the psychological processes that generate the belief in question are not the sorts of processes that could plausibly result in true, factual beliefs (Nichols 2014) or argue that whatever ends are supported by a theory of Darwinian natural selection – be they the flourishing of the gene, the individual, or the group – such ends cannot be moral ends (Sommers and Rosenberg 2003).

Regardless of these differences, all such accounts have the same strategy of arguing that the best evolutionary account of the origins of humans’ moral faculties and beliefs will refer to their fitness-enhancing properties, which have no bearing on whether or not the beliefs track mind-independent moral facts. Presumably ancestral humans gained adaptive advantages over their

rivals by cultivating or maintaining certain moral beliefs about themselves and others – whether in-group or out-group members. The differential reproductive success conferred on ancestral humans by adopting these beliefs would lead to their propagation. Humans inherit these beliefs today as part of their cognitive architecture. However, whatever moral beliefs they have as a result of such a process cannot be justified by claiming that they track mind-independent moral facts.

One widely cited account presents a dilemma for moral realists (Street 2006). If evolutionary forces played a pervasive role in the production and maintenance of moral beliefs, what could be the relation between these evolutionarily shaped beliefs and any mind-independent moral facts? There are two options, neither of which is attractive or acceptable, hence the dilemma. The first horn of the dilemma claims that mind-independent moral facts are not at all related to the evolutionary pressures on moral beliefs. But this implies an implausible general skepticism about the truth of many commonsense ethical claims, even intuitive claims such as that it is right to take care of one’s children. This is because even though this judgment seems obviously true – indeed, true in a way that does not require the endorsement of any particular person’s beliefs – ancestral humans would have not converged on this belief because it referred to a mind-independent fact. Instead, those who had such beliefs were simply more fit than others. The second horn of the dilemma claims that there is, indeed, some relation between mind-independent moral facts and the evolutionary pressures on moral beliefs. The ancestors of modern humans reaped adaptive advantage precisely by means of tracking independent moral truths. However, this leads to a different, but no less serious, problem: it requires some plausible “tracking” account, and, *any* such account seems otiose. It would be more parsimonious to leave out mind-independent moral facts and just focus on the adaptive links that ancestral humans forged between their circumstances and their responses to those circumstances. The latter account would also have greater explanatory power through its ability to describe how they had beliefs that

contemporary society now regards as false (like the tendency to prefer in-groups to out-groups; Street 2006, p. 134). By contrast, a tracking account fails to easily explain the origin or persistence of such false beliefs.

Joyce (2006, 2016) makes a similar argument, criticizing accounts of moral judgment that attempt to show that evolutionary forces produced in human minds a moral truth-tracking faculty. Joyce focused on the *function* of moral judgment in human beings: could it be to track mind-independent moral facts? Some faculties do appear to be truth-tracking in this sense: mathematical representations seem to track mathematical truth because an organism only derives adaptive advantage from true mathematical judgments and not from false ones. (E.g., a person that judged that $2 + 3 = 6$ would be at a significant disadvantage compared to another that judged that $2 + 3 = 5$). However, as Joyce argues, there is no comparable benefit to making true moral judgments. The moral faculty (such as it is and putting to one side the question of whether such a faculty even exists) does not appear to give its bearers advantage on the basis of its truth-tracking (Joyce 2006). Instead, to the extent that a moral faculty can be given an evolutionary explanation, it appears to have given ancestral humans an advantage in virtue of its other (non-truth-tracking) features, for example, signaling one's sincere commitment to social projects or maintaining one's reputation in the group (c.f. Miller 2007; Nesse 2009). Since one should not expect moral judgments to do anything other than what they were selected for, and since they were not selected for truth-tracking, this provides a plausible reason for doubting that moral judgments are formed by a reliable process.

Many theorists have argued that in the absence of good arguments against the justification of moral beliefs, those beliefs ought to be regarded as justified (Wielenberg 2010; Enoch 2011). However, the arguments above turn the tables on any such account when applied to the moral domain. Any account which claims that there exist moral faculties that in fact track objective moral facts must now present plausible explanations arguing for the existence of such facts and

their respective faculties. Given the success of evolutionary accounts to provide explanations for a range of phenomena, the burden of proof shifts to those who wish to defend mind-independent moral objectivism.

Evolution's Contribution to Perceived Moral Objectivity

However, even while maintaining that mind-independent moral facts are a fiction, Joyce (2006) nonetheless speculated that a tendency to see morality in objective terms is an evolutionary adaptation. Evolutionary forces selected for individuals who were highly motivated to act upon fitness-enhancing beliefs, including moral beliefs. Seeing morality as objective (independent of oneself) would be a much stronger motivator to act than seeing morality as mere subjective preference. For example, when one says that a person ought not to steal, one does not take oneself to be merely asserting that it is within the person's set of current desires that she not steal. Even if she does strongly desire to steal and thinks it a great idea, this has no impact on the fact that she *ought not steal*. The challenge for anyone who endorses moral objectivity is to show exactly how such "categorical imperatives" are possible. The standard approach is to show that every agent (or at least every *rational* agent) has some reason to be moral. This article will not be detained with the details of that discussion. The important point is that when one condemns those who commit atrocities such as genocide, coming to learn that the perpetrators are furthering their goals through genocide would not at all mitigate one's condemnation. It does not matter how the perpetrators feel about moral norms; moral norms apply to them *regardless* of what they feel. This seems a pervasive aspect of moral life.

As noted above, some take this objective categoricity to be a "nonnegotiable" part of the moral domain – a central tenet that any theory of morality must explain. Discovering that such a central tenet is false can reveal the discourse to be systematically flawed. If moral discourse is in fact committed to such categorical judgments,

then evolutionary debunking arguments (as discussed above) will imply moral skepticism. This leaves a question: Why do some philosophers take objectivity to be such a central part of moral discourse and practice to begin with? Why does it seem to be a feature of morality that moral facts exist? Whence comes the perception that morality is mind-independent in the first place?

Here, it may be instructive to separate two issues, following Edouard Machery and Ron Mallon (2010). The first concerns why one would be expected to adopt norms of behavior that, in general, come with costs and may serve to stifle or frustrate some of one's current desires. Call this "normative cognition," involving such concepts as "should" or "ought" or "ought not." It is rather uncontroversial that humans have evolved to pick up on prevailing norms in their groups (whether these norms are implicit/informal or explicit/formal), assimilate or internalize them, and feel motivated to adhere to them. Normative cognition also includes expectations that others comply with the same norms, along with a desire to sanction or punish those who do not. Finally, normative cognition can be accompanied with feelings of guilt and shame if individuals fail to adhere to norms that they have come to adopt or endorse. Indeed, people are, in general, adept at reasoning about norms (Cosmides and Tooby 2005).

However, any such account of normative cognition will not require anything like the sort of mind independence that moral objectivism entails. Normative cognition can include esthetic matters (e.g., how one ought to dress), prudential matters (e.g., how one ought to climb the mountain), or matters of propriety (e.g., how one ought to lay the dinner table). These all seem to depend, in some way, on the existence of contingent motivations in individuals to adopt them; *if* one wants to appear beautiful or be prudent or adhere to etiquette, then one ought to adopt certain norms of behavior. But, as just noted, moral norms seem to be different from these norms. Moral norms apply regardless of a person's contingent preferences or desires. How can one, then, explain the emergence of distinctively moral norms of this objective kind?

Some have speculated that *moral* cognition – that is, a form of cognition that sees certain norms as mind-independent, factual, inescapable, and nonnegotiable – was an evolutionary adaptation of our species to spur us to prosociality (Joyce 2006). Joyce (2006), for example, speculated that even though mind-independent moral facts are entirely fictional, it would have been beneficial for our species to have evolved a tendency to think they exist. A tendency to see the world as filled with such mind-independent moral facts would be a much stronger motivator to act prosocially. Thus, humans project objective moral facts into the world through our emotional reactions to morally relevant events. Goodness and badness, virtue and vice – these are not properties that exist in the world to be perceived by the mind. Instead, the mind *projects* these values into the world, which then motivates individuals to act according to moral norms. Thus, evolution selects for a capacity to objectify morality even while moral facts do not exist. This account, while speculative, merits further research.

Responses to Evolutionary Debunking

Those who aim to secure objectivity in ethics have responded to evolutionary debunking arguments in a number of different ways. On the one hand, some have offered *third-factor accounts* that purport to show that moral judgments do track moral facts even though they were not selected for this purpose. On the other hand, some have argued that the standards of reliability being invoked in debunking arguments are too strong; if they were adopted for other areas of common knowledge, this would lead to an untenable radical skepticism. These two approaches constitute well-developed contributions to the debate about the implications of evolution for moral objectivity, and they will be considered in turn.

Third-Factor Accounts

The most prominent response to evolutionary critiques of moral objectivity involves arguing that

moral judgments do track real moral facts. However, they do so as a by-product of some other epistemically respectable cognitive faculty. The strategy is straightforward: if a plausible evolutionary story can be told about how humans came to track objective moral facts in spite of the adaptive pressures which influenced ancestral humans' moral judgments, this might secure the reality of objective moral facts and maintain their objectivity at the same time. Different proponents of this type of response have different capacities in mind when they propose such "third-factor" accounts – accounts about some third factor that humans evolved to track that happens to also align with moral facts.

Enoch (2010) puts forward a quintessential third-factor account, which starts from the premise that survival is (on balance) a good thing. The advantage of such a starting point is that it is fairly obvious that adaptive pressures on ancestral humans did tend to favor their survival. He then argues that by making choices that assured their own survival – a good thing (on balance) – ancestral humans were in fact tracking moral facts indirectly. They developed the judgments they did because those judgments were adaptively advantageous, and it just so happened that such those judgments tracked moral facts as a by-product. Put another way, the capacity to track moral facts was not directly "selected for" by adaptive pressures but rather was merely "selected," because it was not adaptively advantageous to separate it from other faculties that were themselves selected for by adaptive pressures. It may be an accident that such an adaptation arose, but once it did, it conferred on ancestral humans a reliable way of making objective moral judgments. The capacity to perceive moral facts might be like the capacity to perceive stars (Huemer 2005); having the capacity to see stars did not itself give early humans any adaptive advantage but rather came about from other capacities that did confer such adaptive advantage. Other candidates for such third factors include the badness of pain (Skarsaune 2011), the importance of having personal boundaries that others cannot transgress (Wielenberg 2010), the goodness of altruism (de Lazari-Radek

and Singer 2012), cooperating with others (Brosnan 2011), or enhancing society's ability to meet its needs (Copp 2008). Each of these appeals to capacities or tendencies which enjoy better evolutionary pedigree than any purported faculty of moral judgment.

Nonetheless, Street (2006) objects to third-factor accounts on the grounds that these accounts are themselves vulnerable to a Darwinian dilemma: whatever capacity tracks this third factor must itself have been selected for as a result of adaptive pressures on ancestral humans. The question, then, is what the relation would obtain between objective moral facts and the evolution of this capacity. If there is no relation, Street says, this looks like an implausible and convenient coincidence. If there is some relation, then the realist must specify what that relation is. But, she argues, the capacity that allowed early humans to (indirectly) track moral truth would have to be fairly specialized and complex. It is implausible to think that such a specialized and complex capacity could have arisen as a by-product of some other cognitive capacity (Street 2006).

Proponents of third-factor responses generally deny the claim that grasping moral facts really requires a complex or specialized capacity in the first place. For instance, de Lazari-Radek and Singer (2012) argue that this capacity simply springs from our ability to reason in general, which is the same capacity involved in grasping other types of *a priori* truth (like truths of mathematics; see also FitzPatrick 2014). Similarly, the capacity to track facts about pain is not specialized or problematically complex (Skarsaune 2011). (For a more general defense of third-factor accounts, see Berker 2014.) If the capacity is suitably general, this allows the third-factor proponent to say that the relation between moral truths and the capacity which tracks them are unproblematic: humans track moral truths by their capacity to reason, and this capacity has an excellent evolutionary pedigree.

Finally, it should be noted that all third-factor responses invoke a moral assumption from the start, whether it be the goodness of survival, the badness of pain, or any of the other candidates. Thus, another prominent objection to third-factor

responses targets the legitimacy of this move. Street argues that any such assumption is “trivially question-begging,” because it simply assumes the reliability of our moral judgments, but those are the very judgements which the evolutionary critique is meant to undermine (Street 2008, pp. 216–217). This brings us to the second major response to evolutionary critiques: the overgeneralization response.

The Overgeneralization Response

The second response to evolutionary critiques of moral objectivity seeks to undermine the epistemic standards implicit in these critiques. This approach tries to show that if these standards were adopted universally, they would imply radical skepticism. This has also been dubbed “the containment problem” for evolutionary debunking arguments (Millhouse et al. 2016). In fact, some authors argue that the source of doubt implicit in these evolutionary critiques does not derive from evolution at all but rather an unjustified suspicion about the genealogy or causal history of any source of knowledge.

Evolutionary critiques of moral objectivity largely trade on a suspicion about the genealogy of certain beliefs, but the epistemic standards that lie behind this suspicion are not often well articulated. As was covered above, the problem introduced by evolution seems to be that adaptive pressures on the moral judgments of ancestral humans were not tracking mind-independent moral facts, and this seems to undermine their reliability. But one can further ask exactly what about this lack of truth tracking seems to undermine the objectivity of moral judgments. One possible thought is that if judgments are not tracking mind-independent moral facts, this means there is no good reason to believe they are true. In general, if one has no good reason to believe that a belief is true, one ought not to maintain it (Vavova 2014).

Though this standard looks quite reasonable at first glance, proponents of the overgeneralization

response think it goes too far. Crucially, it depends on whether a “good” reason is one that must come from outside the realm of moral judgments themselves. Street (2008) argues that “third-factor” accounts are trivially question-begging, because they rely on moral beliefs in the first place, which are themselves questionable on evolutionary grounds. However, proponents of the overgeneralization response think this argument implies far too exacting a standard. The reason is that if a “good” reason is one that must be independent of *all* moral judgments, a similar argument can be made about other sources of knowledge, for example, sense perception. Most people believe they are justified in believing the deliverances of their immediate sense perception, at least for medium-sized objects in conditions of sobriety and good lighting. But if they were asked to justify this judgment without reference to any beliefs gained from sense perception itself, they would come up empty-handed (Vavova 2014; Shafer 2012). This constitutes a clear *reductio ad absurdum*: if evolutionary critiques of moral objectivity rely on an epistemic standard that would also undermine perceptual beliefs, this is a good reason not to accept that standard and therefore also a good reason not to accept the critiques.

At this point, the proponent of an evolutionary debunking argument might grant that some judgments in the one domain can justify other judgments in the same domain (whether it be perceptual or moral). Relaxing epistemic standards in this way, however, risks allowing third-factor accounts a metaphorical foot in the door. If one is allowed to assume that one’s judgments about the objective badness of pain or the objective goodness of survival are justified (despite the adaptive pressures which caused early humans to make such judgments), many of one’s more substantive judgments can be justified on the basis of these judgments (Vavova 2014).

On a similar basis, some proponents of this response argue that evolutionary considerations can only fail to *vindicate* moral judgments but that they are not capable of producing any

independent *skepticism* about the reliability of moral judgments (Brosnan 2011; FitzPatrick 2014; White 2010). This can be shown by imagining a situation of total ignorance of the source of moral judgments. If one has no knowledge of evolution's influence on one's judgments, would this in any way improve the justification of one's moral beliefs? The answer seems to be "no." If total ignorance of the origins of one's moral beliefs does not improve one's epistemic lot, it is unclear how the truth of evolution's impact on one's beliefs could make it any worse, short of showing that these judgments are actually "anti-reliable." All that evolutionary debunking arguments can show is that moral judgments are made in a way that is independent of their truth, but this does not in itself imply that they are unreliable (see Brosnan 2011; White 2010).

A related point concerns the metaethical presuppositions inherent in evolutionary debunking arguments. In order to motivate the case against objectivism, these arguments take it to be the case that moral judgment is not truth-tracking. But in order to fail to be truth-tracking, there must be some truth to track in the first place. After all, if it turns out that nonobjectivist accounts of moral facts and concepts are correct, and these things depend in some way on human attitudes, it is not clear how evolutionary influences might undermine them (Kahane 2011).

As was covered in the section on "third factor" accounts above, determining the burden of proof in this disagreement is quite difficult. Joyce (2016) claims that given the fact that there is good reason to believe that humans' faculty of moral judgment was not selected for tracking mind-independent moral facts, the burden rests on the realist who wants to claim that it does so. But if the overgeneralization critique of this argument is correct, it is not clear that the burden of proof rests on the realist after all. It would seem that the proponent of an evolutionary critique must show how evolution's influences on moral judgments render them not just *independent* of moral facts but also *unreliable*.

The exact connection between these two claims constitutes an area of unfolding debate. Given the implications for a claim that many psychologists and philosophers take quite seriously – the objectivity of morality – quite a lot hangs in the balance.

Conclusion

The relation between moral objectivity and evolution is complex, depending on factors such as the function of moral judgment, what one takes moral judgment to be tracking, and the epistemic standard implicit in our evaluation of moral judgment. Though many philosophers, psychologists, and ordinary people perceive objectivity to be an integral part of morality, there is quite a healthy debate about whether moral objectivity can withstand an evolutionary account of human history. Though there is not yet a consensus, this article has laid out the main fault lines between proponents of evolutionary skepticism and their realist opponents.

Synonyms

Obligatory investment; Parental investment

Definition

Obligatory parental investment refers to the amount of time, energy, and resource expenditures that organisms are minimally required to make in order to ensure offspring survival.

Introduction

Throughout evolutionary history, offspring survival has posed a main adaptive challenge. In some species, this selection pressure has resulted in sex-differentiated forms of parental investment. This chapter describes obligatory parental investment, explores asymmetries in obligatory parental investment between males and females, describes examples of such differences across a range of species, and briefly highlights the implications of such differences in terms of human sexual strategies and conflicts.

Parental Investment Theory

Parental investment is defined as an expenditure of resources made by parents that increases their offspring's fitness at the expense of channeling their resources to other fitness avenues, such as their own survival or mating opportunities (Trivers 1972). Obligatory parental investment thus broadly refers to parental investment that is required in order for offspring to survive.

Differences in Minimum Obligatory Parental Investment

Trivers' (1972) seminal theory of parental investment provides a clear specification of two important components underlying Darwin's (1871) sexual selection theory. These components include intrasexual competition, where members of one sex compete for access to the sexual resources held by members of the opposite sex, and intersexual selection, where members of one sex exert preferential mate choice over members of the other sex. When the minimum obligatory investment is higher for one sex than the other, mating errors (e.g., mating with low-quality mates) tend to be more costly for the higher investing sex. Accordingly, the higher investing sex tends to evolve to be choosier, whereas the lesser investing sex tends to evolve to be more intrasexually competitive in order to gain access to the more reproductively valuable sex.

Offspring production and survival in mammals necessarily relies on internal gestation and postpartum suckling through the mother. These physiological requirements on the part of mammalian females, but not males, produce a typical sex difference in minimum obligatory parental investment for mammals (Trivers 1972). Mammalian females therefore typically invest significantly more in their offspring than males, and humans follow this general pattern of mammalian discrepancy in obligatory parental investment – women's minimum obligatory parental investment includes approximately 9 months of pregnancy and is often associated with years of lactation and nurturance during the child's formative years. In comparison, men's minimum obligatory investment is a single sperm and can end with a single act of sexual intercourse; additional paternal investment during the child's formative years is not essential for the survival of the child to reach adulthood (Goetz and Shackelford 2009; Trivers 1972).

For many species, including humans, females are the high-investing sex and, as such, have evolved to be more careful and discriminant compared to males in mate selection and are thus more likely to promote intersexual selection by exercising greater preferential choice over mates. This in

turn drives intrasexual competition in the low-investing males, because they need to contest against other males who are also eager to gain access to the discriminate and selective females (Buss and Schmitt 1993).

Examples of Parental Investment Theory

These sex differences in intersexual selection and intrasexual competition that arise from discrepancies in minimum obligatory parental investment can be observed in a wide variety of species. For instance, in elephant seals, pups are nursed solely by females; males do not partake in any paternal care and sometimes even kill their own pups by accident when they attempt to copulate with mates in the harem, underscoring the much larger parental effort and investment on the part of females. The value of the sexual and parental resources provided by females is matched by extreme male competitiveness – indeed, less than one third of males have a chance to copulate during any breeding season because the highest rank males secure at least half of all the matings (Le Boeuf 1974). As the desirability of a male as a mating partner is based on his standing in the social hierarchy, female intersexual selection of mates is facilitated by contests between rival males for dominance, and adult males arrive at the beach during breeding season and fight intensely with each other. The winners of the fights become the highest-ranked males, and females then choose these high-ranking dominant males to be their mates.

Intrasexual selection drives the evolution of exaggerated traits, displays, and behaviors in the males of various species, as can be observed from the large antlers of stags and tusks of elephants. Among the satin bowerbirds, males do not partake in any offspring care nor associate with females after mating. However, courtship is quite elaborate and competitive. Males build large, specialized, and highly decorative nest structures known as bowers in order to impress females, and females exercise selectivity based on the males' bower-building prowess (Borgia 1985).

In contrast, females in these species tend to be drab and are designed not to impress but to exercise choice. Interestingly, in insect species such as the water strider, females have evolved abdominal spines, which hinder the efforts of unwanted males and reduce the frequency of costly, unchosen matings.

Although heavier obligatory parental investment is more commonly observed in females than males, the pattern is reversed in some species. Consistent with parental investment theory, where males contribute a larger obligatory parental investment than females, the sex role is reversed and the males of those species are the more selective sex while the females intrasexually compete for the males (Trivers 1972). In a bird species known as the *Phalaropus lobatus*, the female phalarope's obligatory parental investment only consists of laying the eggs in the nest. The male phalarope, on the other hand, builds the nest himself, incubates the eggs, and looks after the young alone. As predicted by parental investment theory, the females aggressively court the males and compete with each other to be selected by the males (Johns 1969). Another example of a sex role reversal can be found in pipefish and seahorses. During mating, the females transfer their eggs onto specialized egg-brooding structures located on the males' tails, where they are nourished throughout the entire duration of gestation. As the lesser investing sex, the females evolved to be brightly colored in order to compete intrasexually to be selected by the higher investing males, who evolved to preferentially choose the most attractive and brightly colored females as their mates (Wilson et al. 2003).

Taken together, discrepancies in minimum obligatory parental investment between the sexes drive the operative components of sexual selection, with the higher investing sex (who faces greater mating costs) evolving to be choosier and the lower investing sex (with lesser mating costs) evolving to be more competitive with members of their own sex for mating opportunities and access to the more valuable high-investing sex.

Implications of Asymmetrical Obligatory Parental Investment for Human Sex Differences and Mating

In humans, differences in obligatory parental investment between males and females gave rise to a host of implications for sex-differentiated mating strategies. This section briefly highlights a few key sex differences between men's and women's mating strategies as predicted by their relative obligatory parental investment.

Sexual Strategies

Asymmetries in obligatory parental investment between the sexes present different constraints for the sexes and, accordingly, have led to the selection of sex-differentiated sexual strategies. In particular, offspring carry much higher costs to women than men if they result from uncommitted sex, particularly for ancestral females who lived without modern-day benefits such as easier access to food and social welfare. Thus, in reproductive terms, the costs of non-committed, casual sexual relationships typically outweigh the benefits for women more so than for men (Li and Kenrick 2006). As such, women, compared to men, have evolved to prefer a selective, long-term mating strategy in order to procure the commitment of a mate who can continually provide protection and resources. Men, on the other hand, do not face this constraint, and their reproductive success is largely constrained by the number of sexual partners to which they have access. As such, men, more than women, have evolved to pursue a short-term mating strategy in order to increase their access to a wider pool of sexual partners (Buss and Schmitt 1993). Consistent with these differences, a classic study found that when approached and propositioned for sex by an attractive member of the opposite sex, a large majority of college men agreed, whereas not one woman consented (Clark and Hatfield 1989).

Sexual Conflict

As a result of asymmetrical obligatory parental investment and the sexes pursuing different

optimal sexual strategies, men and women may often come into conflict. As men have a stronger preference for short-term relationships and stand to benefit more from multiple matings than women, men have a stronger desire for sexual variety and are more sexually persistent. Asymmetrical preferences between the sexes predict that men are more likely than women to pursue sex with partners who are reluctant or unwilling (Buss and Schmitt 1993). Studies have found that men are more likely than women to perceive that a woman is sexually interested based on minimal social cues such as a smile, a touch on the arm, or mere friendliness (Haselton and Buss 2000). This sex difference in perception has been proposed to reflect a male sexual overperception bias that evolved given the asymmetric reproductive costs to men of making inferential errors. That is, in judging whether a female is sexually interested in ambiguous situations, there is a greater reproductive cost associated with incorrectly inferring no interest and missing a potential sexual opportunity compared to mistakenly inferring sexual interest and wasting a bit of time and effort. As such, a male bias to overperceive sexual interest induces, on average, more instances of the less costly error while facilitating the enactment of a short-term mating strategy.

In contrast, women's higher obligatory parental investment, which leads to stronger preferences for committed long-term relationships, makes them more sexually restricted than men (Buss and Schmitt 1993). Women are therefore less eager and thus more likely than men to thwart the sexual advancements of the opposite sex. In line with evolutionary constraints favoring a choosy strategy, women may have evolved to be skeptical about a man's commitment even when it may be sincere, as the reproductive costs to women of wrongly inferring that a man is committed are large compared to the costs of requiring further signs of commitment before engaging in sexual relations (Haselton and Buss 2000). Further, as women value resources in a mate and seek mate quality over quantity, it is in their interest to "lead on" the other sex and entice further investments or induce intrasexual competition in the

opposite sex. For instance, a woman might dress provocatively and engage in flirtatious behavior despite having little or no sexual interest so as to attain more investments from interested suitors, or get them to compete so that she can enact a selective strategy and choose from the best competitor.

Together, these opposing interests arising from asymmetries in obligatory parental investment likely contribute to women's experience of unwanted sexual advances (Goetz and Shackelford 2009) and men's frustration with failed and protracted courtships. Indeed, it has been argued that differences in evolved mating strategy underlie historical and cross-cultural patterns whereby men are more likely than women to be the perpetrators of sexual coercion and rape, while women are more likely than men to be the targets (Goetz and Shackelford 2009).

Conclusion

Reproductively successful parents have enacted sexual strategies and mating behaviors that optimized their own reproductive fitness over evolutionary time, and these behaviors are a reflection of, as well as a response to, obligatory parental investment asymmetries. Across many species, including humans, females have a greater minimum obligatory investment than males to ensure offspring survival, which has tended to select for sexually choosy and discriminating females and sexually eager and competitive males. These sex differences in parental investment and mating costs have implications for men and women in terms of differences in their preferred sexual strategies, their judgments of potential mates, and the type of mating conflicts they experience.

Definition

Altruism can generally be understood as voluntary behavior which benefits another organism(s) but that demands from the benefactor a certain sacrifice, that is, an action that increases the beneficiary's aptitude at the cost of the benefactor's aptitude. In this sense, self-sacrifice is a hallmark of altruism, given that it can sometimes involve risk, be unhealthy, or even be dangerous.

Introduction

More and more people are recognizing the importance of behaviors aimed at benefiting others (i.e., pro-social behaviors). This signals the importance of becoming aware of the implications of such actions for society as a whole. Of the different psychological phenomena, altruism stands out, this in view of the potentially high cost to the benefactor. This is true specifically in the case of human beings, which demonstrate their potential to act for the other in various ways, such as donating blood or organs or even giving money to unknown needy people in a recognizable situation.

However, the reader might now be wondering: How does evolutionary psychology understand altruism? Altruism is a complex phenomenon that has been discussed under differing conceptions such as *kinship selection*, *reciprocal altruism*, and *group selection*. *Altruism by kin selection* predicts the reproductive success of individuals who are genetically linked (i.e., kinship), even though it may risk the reproduction or survival of the helper. *Reciprocal altruism* refers to another perspective that defends the idea that the individual momentarily diminishes his own aptitude in order to favor another, in the hope of the latter returning the favor later. Finally, the *group selection* approach affirms that altruism has evolved because it increases the overall fitness of the group, affecting both group and individual outcomes. Aware of the existence of different notions about altruism, this entry aims not to resolve this

theoretical impasse but to seek a better understanding of how altruism comes to be expressed.

The evidence indicates that the origin of altruism in different species lies in the quality of the parent-child relationship (Batson 2012). However, in order to behave altruistically, it is first necessary to identify the goals of the other and the difficulties that exist toward achieving them (Warneken and Tomasello 2006, 2009). A particularly informative behavior for the study of altruism is that of instrumental aid, in which an individual performs an action in support of another, with the purpose of making him achieve a concrete goal (Warneken 2010). Based on this approach, the altruistic action is evaluated from observation of instrumental helping behavior; this form is configured as one of the first types of altruistic expression in human ontogenesis (Warneken and Tomasello 2009). Yet it remains essential to note that altruism is expressed in different ways, such as solidarity, comforting, sharing, cooperating, and caring for others, among others (Warneken and Tomasello 2009).

Study of this modality of behavior in nonhuman primates has been an enriching source of information for understanding the phylogenetic aspects of this construct. In this regard, the literature argues that nonhuman primates apparently have potentials, such as motivational and cognitive skills, which enable them to engage in altruistic acts (Tomasello 2010). Nevertheless, the results concerning the expression of altruistic behavior in nonhuman primates are still controversial (Warneken and Tomasello 2006). In view of this, one might ask the question: What causes nonhuman primates to engage in behavior favoring others in some situations, but not in others?

Evidence has shown that this may be conditioned upon a necessity for an expressive demonstration of wanting or needing help (Warneken and Tomasello 2008), such as the case of a nonhuman primate observing that an individual of his species is trying to reach food that is outside of their reach. Corroborating this perspective, the literature has pointed out that as with human primates, nonhuman primates are apparently also able to identify when another individual requires assistance (Warneken and Tomasello 2006).

Studies show that mechanisms and behaviors in human and nonhuman primates are similar

(Warneken and Tomasello 2006) until a certain age, but at some point (early in ontogenesis), they begin to differentiate, with humans showing greater diversity and sophistication in the expression of altruism (Warneken and Tomasello 2009). The literature has pointed out that nonhuman primates help one another in instrumental aid contexts (Warneken 2010), so it is admitted that they exhibit behaviors understood to be altruistic even though in a smaller variety of situations as compared to humans (Warneken et al. 2007).

In asking about the factors that may affect this differentiation as to the quantity and quality of altruistic behaviors, one notes the influence of cognitive factors. Indeed, cognitive ability plays a fundamental role in the performance of altruistic acts. This can be observed among other animal species (Stevens and Hauser 2004; Warneken and Tomasello 2009), even though other species engage in pro-social behavior less often than humans (Stevens and Hauser 2004). Also according to these latter authors, such situations can be understood in that altruistic actions can go well beyond simple problem identification and require resolution of complex problems to help the other. This would explain restrictions in altruistic behavior in nonhuman animals, since sometimes the aid demands notions involving estimation of time, learning, and memory.

In altruism, the physiological and hormonal influence of the hypothalamus, oxytocin, and peptide hormones on altruism has been increasingly observed. In this sense, there is now evidence of greater activation of these hormones and areas when individuals are involved in romantic and parental-offspring (caring) relationships. It is believed that such bonding modalities and the exercise of social roles have respective links to the construct in focus here, such that altruism influences them, contributing to the choice of romantic coupling (Stavrova and Ehlebracht 2015) or even affecting the quality of parental care (Swain et al. 2012).

In discussing aspects related to observations of altruism, one cannot fail to mention the influence of both culture and the magnitude of the force it exerts on psychological phenomena. Culture is part of the individual and acts as a guide for human behavior; it defines the traits and

behaviors which are valued in every social context. Despite the similarities among the most varied cultures as to altruistic behavior, Bowles, Choi, and Hopfensitz (2003) note the existence of differences in manifestations and cultural practice among various groups and contemporary societies, such that even neighboring groups present particularities in their forms of altruistic expression.

Conclusion

Evolutionary psychology has made important contributions to the understanding of the origins of altruism, and differing perspectives have contributed to understanding phylogenetic aspects, such as kinship selection, group selection or even reciprocal altruism. Indeed, altruism is a psychological phenomenon that, although controversial, has been increasingly recognized for being instrumental in increasing the fitness of various species. However, no consensus has yet been reached as to its motivations and evolutionary components.

This psychological phenomenon can be observed in human and nonhumans, and its primary or basic form of expression is instrumental aid. However, for an individual to engage in an altruistic action, it is necessary that he understands both the objectives of the subject in need and the obstacles that the individual needs to overcome. Thus, the cognitive component is a basic factor in the expression of altruism and is an important differentiating element both quantitatively and qualitatively in the various altruistic expressions found in humans and other animals. Despite relevant scientific advances, it seems that there remains a considerable distance to go until we fully understand this intriguing psychological behavior. In this field, more research is clearly needed.

Definition

Sexual dimorphism is the term used to describe when the two sexes of a species possess physical characteristics that differ from each other. These physical characteristics can include differences in height, weight, color, decoration, and pattern and can even include body parts unique to one sex or behaviors such as birdsong.

Introduction

Evolutionary psychologists are interested in human sexual dimorphism (the observation that men and women tend to have different physical qualities), and whether it constitutes an evolved signal of some kind. There is a large body of evidence that this is the case for nonhuman animals, for example, the peacock's tail which signals mate quality to the peahen; and the antlers of some deer species which signal to rivals the dominance of the deer. This chapter will report some of the evidence suggesting that similar signals occur in humans, as well as evidence that suggests they do not. Specifically, it will focus on two areas: *male ornamentation*, physical characteristics that males possess which seemingly do not help with survival chances but do help with reproduction chances, and *costly signalling*, the fact that signalling can use an animal's nutrients from food to grow an ornament at the cost of maintaining the animal's overall health or increase the risk of death by predation.

Male Ornamentation

When observing nonhuman animals, sometimes the two sexes of a species will look noticeably different from each other. When each sex of a species has physical qualities that are unique to that sex, or that differ quantitatively between the sexes, this is considered *sexual dimorphism* (from the Greek *dímorphos* meaning "having two shapes"). There are many types of sexual dimorphism in the animal kingdom. Sometimes, the two sexes are different sizes, such as with the blanket

octopus, whose females can be up to 40,000 times heavier than the males, or the colors of the animal can be quite different between the sexes, such as the many species of birds known for the stark difference between their brightly colored males and milder-colored females.

Although it is not always clear why these differences exist, evolutionary theorists have gathered evidence of the process behind their evolution, namely *sexual selection*. Instead of characteristics being selected because they help the animal survive (*natural selection*), some characteristics are selected because they help the animal gain access to mates, and this is what is called sexual selection. Sexual selection can lead to characteristics that help an animal in the mating market by giving it the means of winning the competition with its same-sex competitors, or by making it more attractive to the opposite sex.

This assessment is reinforced by the observation that some of the differences between the sexes appear to be purely decorative. Which is to say that it seems the specific characteristics have no use for the animal's survival, they just appear to be *ornamentation*. These ornaments appear far more often in the male of the species, rather than the female. This is driven by what is known as the males-compete/females-choose model of selection which most sexually reproducing animals follow. In such systems, males compete for access to females, and/or females choose which male to mate with. Under this model, ornaments do serve a function. They are communication devices or *signals* to other animals of the same species.

In order for a characteristic to be considered as an ornament, it needs to meet some criteria. First, it must be a *secondary sex characteristic*. Secondary sex characteristics are features that are used in the process of sexual selection but are not directly used for sexual reproduction. Second, it must correlate with some underlying quality of the animal. This could be an aspect of the animal's health or an aspect of the animal's behavioral temperament. And third, there needs to be evidence that the other members of the species actually use the signal as an indication of the underlying quality.

Ornaments can take on many forms. They can be qualities of the physical body, such as the

bright colors of the mandrill's face; elaborate patterns like those of the golden pheasant's feathers; or strangely shaped body parts like the hooked jaw of spawning salmon and trout. They can also be behaviors, such as the birdsong of the Australian whipbird; or the elaborate dances of the peacock spider.

The peacock is the most commonly used example of male ornamentation. It has elongated tail feathers with some of those feathers looking like large eyes (ocelli). Research has shown that the length of the male's tale feathers is positively correlated with overall body condition (Moller and Petrie 2002), so the peacocks with the longest tails are also generally the healthiest peacocks. Other research has discovered that during mating season, the peacocks with the most ocelli are the ones which mate with the most peahens (Petrie et al. 1991). With these two observations linked, it can be said that the peacocks with the longest tails are also more likely to have the most ocelli (more space on the larger tail to fit them in) and mate with the most peahens. So, we can see that the ornament is related to an underlying quality, and the opposite sex is using the ornament to make mating decisions, i.e., finding the healthiest peacocks in order to increase the chance that her chicks will be healthy too. This is an example of the ornament being used to communicate something to the opposite sex, but ornaments can be used to communicate to the same sex as well.

Ornaments can also communicate something about the animal's temperament or expected behavioral patterns. The fallow deer is a species found in many places around the world, due to its introduction from European origins. The mature bucks grow a new set of antlers every year before their mating season. The antlers are shovel-shaped, with some spike-like growths around the edges. Research has shown that the total number of these spikes and the dominant behavior of the bucks are positively correlated (Pélabon and Joly 2000). This finding, combined with the fact that, although the bucks do use the antlers for fighting, they are the main source of determining status in the male hierarchy *without* fighting (Lincoln 1972). Due to the likelihood of injury during a battle, it can be more effective to use the antlers as

a signal of which bucks to avoid. There has also been some conflicting evidence regarding the symmetry of the antlers, with Malyon and Healy (1994) finding that fluctuating asymmetry correlated with dominance, but Pélabon and Joly (2000) finding that it did not. It is also important to note at this point that the antlers are not strictly ornamental, as they do serve a function in fighting; therefore, the argument could be made that they are technically armaments.

Humans are dimorphic as well. There are differences in the average weight, height, bone density, muscle and fat distribution, and facial structure between the sexes (Burke and Sulikowski 2010; Gangestad and Scheyd 2005). Just as biologists and ethologists use theories of evolution to explain the function of dimorphism in nonhuman animals, evolutionary psychologists can use the same theories to explain the function of dimorphisms in humans. However, data to date suggest that humans are more complex than other animals in this regard, and it is not always clear what constitutes an ornament in humans. This may be because although they still exist, human ornamentations are less extreme than those seen in some other animals. While there are strong body shape dimorphisms in humans, which reflect greater muscle mass and strength in males, and differential fat distribution and pelvic structure in females, many of these differences might plausibly be related to being better able to perform sex-typical roles in traditional societies, and so, even though there is evidence to suggest that these differences may operate as signals/ornaments (e.g., hand-grip strength, Gallup and Fink 2018; waist-to-hip ratio, Singh 1993), the emphasis here will be on facial dimorphisms, since they are more likely to be pure ornamentation.

Facial masculinity is one possible ornament in human males. When the overall composition of the face, including the bones, fatty tissue, skin, and facial hair characteristics, aligns with those which are more likely to be found in men's faces, the face is considered to be masculine. Generally speaking, men will have wider jaws, larger chins, larger width-to-height ratio of the maxilla (the top section of the jaw), and a larger brow ridge relative to a woman of the same body size. Compared

to women, less fat is deposited in the cheek area, skin tone is generally darker, as are eyebrows, and of course, men are much more likely to be able to grow beards (Gangestad and Scheyd 2005).

Researchers have found that masculine facial characteristics are an indicator of underlying sex hormone ratios. Testosterone (found in greater quantities in men) is involved in the building of bone structures, while estrogens (found in greater quantities in women) suppress bone growth (Kung 2003; Neave et al. 2003). Additionally, masculine facial characteristics develop fully in structure during puberty, when there is an increase in sex hormone levels. This is another indication that facial masculinity is an ornament, as ornaments tend to develop in other animals as they reach reproductive maturity.

Based on these findings, it can be said that the level of facial masculinity seen in a man's face may be a signal of the measure of testosterone circulating in his system. This is important to prospective mothers and future children because testosterone promotes both morphological and behavioral differences.

A greater level of circulating testosterone has been found to lead to more aggressive behaviors and a reduction in pro-social behaviors. It has been shown that as circulating testosterone levels increase, so do levels of physical aggression, verbal aggression, anger, and hostility. Additionally, as levels of circulating testosterone increase, levels of altruistic and empathic behaviors decrease (Harris et al. 1996). As it would be in a prospective mother's best interest to provide a safe and nurturing environment for future offspring, it would be reasonable to assume that she would avoid those males signalling greater levels of aggression. However, in our ancestral past, a certain level of aggression would have been adaptive. An aggressive male would have stood a better chance of climbing the social hierarchy, thus making him more attractive; but he also would have stood a better chance protecting his family from other men wishing to take his mate and/or resources.

More evidence supporting this hypothesis is the fact that both women and men will judge images of highly masculine male faces as

belonging to a more dominant person, while less masculine faces are judged as less dominant (Windhager et al. 2011). However, although the relationships between testosterone and both aggression and physical dimorphism are well established; perceived dominance shows a relationship with testosterone which is not entirely clear. Neave et al. (2003) studied a group of males by taking measurements of both prenatal levels (2D:4D ratio) and current circulating levels of testosterone (salivary measure). They found that prenatal levels of testosterone are related to perceived levels of dominance, but the current circulating levels of testosterone are not. This indicates that greater levels of prenatal testosterone do indeed organize the bone structure of the face to make it appear more masculine and dominant. But, as the levels of prenatal testosterone and current circulating levels were also not related, this calls into question the relationship between facial masculinity and actual behavioral outcomes.

The males-compete/females-choose model has been cited as the reason behind ornamentation of males, but what if the roles were reversed? As predicted by Trivers (1972), when the parental care roles are the opposite of the norm, males can be choosy and females can evolve ornaments. For example, some female pipefish, seahorses, and seadragons are more ornate than the males. It is the males that carry, give "birth" to, and care for the young, and therefore, it is the females that work for the attention of the males.

A second model of sexual selection can also result in female ornamentation. The mutual mate choice model predicts that when both sexes compete intrasexually, and both sexes are choosy about mate selection, then both sexes could use ornamentation. This is the case in humans. Just as facial masculinity is considered an ornament in men, facial femininity is considered an ornament in women. As mentioned previously, testosterone is related to facial masculinity; but for facial femininity, there is a similar relationship with estrogen and progesterone (Law Smith et al. 2006). In women, these two sets of hormones are found in greater quantities, and they are responsible for maintaining and controlling the menstrual cycle.

In other words, they are related to a woman's fertility, and so the femininity of a woman's face is a potential signal of her fertility.

Costly Signalling

As has been explained, ornaments are a type of signal. In evolutionary theory, *signal* has a specific meaning. It is a characteristic of the animal that is used to communicate a specific message. It is done "intentionally" by the signaler (but rarely consciously), and its message is intended to be clear to the receiver, resulting in a behavioral change that is beneficial to both individuals. *Cues*, on the other hand, are unintentional, may be detrimental to the animal sending the cue, and may not always be clear in their message. However, if the cue turns out to be a useful communication device, there is the possibility that it evolves into a signal, which is known as the "signaler precursor route" (Laidre and Johnstone 2013). Take, for example, a wolf baring its teeth. This is a definite signal that the wolf is aggressive and about to attack. It is quite possible that this began as a cue, simply because a wolf needs to draw back its lips so it can bite. Those wolves that saw this cue and avoided conflict with the aggressive wolf would have lived longer, and thus reproduced more pups that tended to avoid other wolves when they saw teeth being bared. Additionally, those wolves that bared their teeth before attacking would have also avoided conflict, lived longer, and reproduced more pups that tended to bare their teeth when becoming aggressive. This is a simple example of a mutually beneficial signal, but signaler/receiver psychology can become more complex when the "cost" of the signal becomes high.

In line with the previous example, in order signal to evolve, the benefits must outweigh the costs. One "cost" of the signal is the amount of physical energy or nutrients/resources required to generate the signal, with ornament growth shown to decrease when food sources are low (Zeh and Zeh 1988). Costs are also associated with the increased risk of predation or being attacked by same-sex rivals due to the signal increasing the

visibility of the animal. Another potential cost is the opportunity cost of missing mating opportunities because of the signal. The "benefit" is defined as the increase in reproductive fitness – an increase in the number of offspring the animal produces. In short, if the development of any signal leads to a handicap for the animal's survival, then there must be a greater advantage to the animal's reproductive chances to warrant the cost; otherwise, the genes which guide development of the signal will never make it into the next generation (Zahavi 1975).

Returning to the wolf example, it is reasonable to believe that the cost of baring the teeth would be quite low. The energy cost would be minute, and the likelihood of attack from competitors would be low as well because the signal is expected to actually reduce the likelihood of violent conflict. However, consider the signal this sends to prospective mates. If the wolf were to bare its teeth excessively, then it may be seen as an overly aggressive individual, which puts the safety of future pups at risk. Therefore, the interpretation of the signal must be consistently reliable and accurate – an "honest" signal. That is, a signal must truly be signalling what it is "intended" to signal in order for the communication system to work; otherwise, the system would collapse. So, it can be seen that the cost of a signal needs to be finely tuned in accordance with the benefit to reproductive fitness. For female mammals especially, the cost of favoring a "dishonest" signal can be high from a mating perspective, as mating with the wrong individual can lead to the extremely high cost of gestating, giving birth to, and feeding young which have a lowered chance of going on to reproduce in the future.

For the facial masculinity of human males, one of the greatest costs comes from the negative effects of greater levels of testosterone. Exposure to high amounts of testosterone has been shown to impair the immune system and make it more difficult for the human body to fight off pathogens (Foo et al. 2017). According to the "good genes" theory of mate choice, the display of high levels of testosterone is seen to signal genetic quality (Penton-Voak et al. 2004). The theory predicts that for a male to be signalling his compromised

immune system, then his genes must be of a high quality in order to compensate for this disadvantage; and it is these genes that the female values to maintain health of future offspring. This theory was put to the test by Zaidi et al. (2018) who used a measurement of a genetic marker of immune system competence known as the *major histocompatibility complex*, and a measurement of facial masculinity in close to 2,000 participants. They found no relationship between the two measures. This means that the level of a man's facial masculinity may have nothing to do with his intrinsic levels of health. It is also worth noting that this finding and failures at explaining other mating behaviors (e.g., Jones et al. 2017) have led to the founders of the good gene theory to retract their support for the concept (Buss and Schmitt 2019).

There is another set of ornaments that is, as far as we know, unique to humans. Miller (2000) makes the argument that displays of intelligence such as those made through music, art, and humor are ornaments. He states that they have no other evolutionary function outside of mate attraction. In terms of costs involved in producing these signals, there is a massive resource cost in growing and maintaining the human brain, which is responsible for these displays. But there is also a social cost when these displays are delivered poorly. Take self-deprecating humor for example. This style of humor is received and interpreted through the context of the status of the person delivering the joke. When a higher status person makes a self-deprecating joke, it is seen as a mismatch with reality and the signaler's status is unaffected because it is believed they can "afford" the cost. However, if a lower status person uses self-deprecating humor, the results are different because they appear as self-defeatist or depressed (Greengross and Miller 2008).

Conclusion

Many sexually reproducing species exhibit sexual dimorphisms, including humans. Some of these dimorphisms are considered "ornaments" because they appear to serve no survival purpose; they are

purely for increasing access to mates. These ornaments are typically displayed by the male of the species, but there are exceptions such as humans. Ornaments can be body parts, or behaviors, and are in essence signals that advertise the quality of the individual who possesses them. Each signal presents a cost to the animal's ability to get its genes into the next generation, which must be weighed against the benefit to the animal's overall reproductive fitness.

Definition

Women's mating behavior includes human female sexual development, mate preferences, and strategies to optimize reproduction and long-term mating. Each of these components of mating behavior has been shaped by selection to produce adaptive outcomes.

Introduction

A life history approach to evaluating human behavior can be fruitful for understanding the fundamentally unique nature of women's mating behavior (Luoto et al. 2018; Motta-Mena and Puts

2017). For example, early in development, puberty in humans marks a formative time during which changes in the visuoperceptual system can influence the ability to detect facial cues related to mating behavior and sexual relationships (e.g., sexual interest; Garcia and Scherf 2015; Motta-Mena and Scherf 2017), a crucial developmental transition that, thus far, appears to be exclusive to humans. As young women undergo puberty and begin menstruation, they begin to exhibit relatively cryptic fertile windows in their ovulatory cycle, report experiencing sexual desire and behavior outside of the fertile window, and engage in higher levels of mating competition compared to most female primates.

Following puberty, women compete for, choose, and engage in both short- and long-term relationships with mates during their reproductive lives. To do so, women must learn to navigate complex sexual relationships in adolescence (Motta-Mena and Scherf 2017), compete with other females for mates (Fink et al. 2014), and learn to provide reliable cues to their availability to potential mates, such as sexual ornaments that signal women's residual reproductive viability (Thornhill and Gangestad 2015). Importantly, women's sexual behavior is not constrained to the fertile phase (e.g., as in most primates; Thornhill and Gangestad 2015) and suggests that perhaps women's copulatory patterns across the cycle may reflect a mixed-mating strategy.

In what follows, this entry will discuss women's mating behavior from pubertal development through adulthood, as well as the evolutionary processes that have shaped women's modern mating behavior. While not exhaustive, this entry provides a broad overview of the emergence and development of women's mating behavior and mating strategies.

Pubertal Development

As a crucial life history transition, pubertal development involves the orchestration of anatomical as well as psychological changes associated with sexual maturation. Girls tend to enter puberty sooner than boys (Marshall and Tanner 1969,

1970) and experience a cascade of physical changes that include the emergence of secondary sex characteristics such as breasts, fat deposition on the buttocks and hips, and pubic hair growth, particularly as girls approach the onset of menarche (Grumbach and Styne 1998; Marshall and Tanner 1969, 1970). Estrogen inhibits the accumulation of fat in the abdominal region and stimulates fat deposits in the lower half of the body (Singh 1993), thereby producing a gynoid body shape (Singh 1993).

Fat around the midsection can be quantified with the waist-to-hip ratio (WHR), which is the ratio of the narrowest part of the waist relative to the widest part of the hips (Singh 1993). Before puberty, lower estrogen levels result in more even fat distribution across the hips and abdomen, resulting in a WHR closer to 1 (for review, see Singh 1993). Beginning in puberty and through the reproductive years, the typical range of WHR is 0.67–0.80 (Lanska et al. 1984). While some work suggests that WHR is related to levels of estradiol and progesterone (Jasińska et al. 2004; Zaadstra et al. 1993), other work has found no such association (Jones et al. 2017). The relationship between women's physical attractiveness and the underlying endocrinology thus remains ambiguous.

In addition to these complex physical changes, puberty also spurs profound changes in adolescent psychology (Dahl 2004; Motta-Mena and Scherf 2017). The transition from puberty into the autonomy of adulthood necessitates that typically developing adolescents learn to navigate increasingly complex social relationships in order to succeed in the competitive reproductive sphere. The complex interplay of hormones is simultaneously influenced by neuroendocrine feedback loops from the brain, which are believed to facilitate sexual behavior in adolescence (Schulz et al. 2004).

Further evidence suggests that adolescents are unable to detect facial expressions related to sexual interest until they have undergone puberty (Garcia and Scherf 2015; Motta-Mena and Scherf 2017), suggesting that perhaps puberty is fundamental for the development or onset of adult-like mating preferences. In short, the unique physical and psychological changes adolescents must

undergo during puberty raises compelling questions about changing social behavior, and how puberty impacts sex-typical social behaviors in adulthood.

Mate Preferences

Women experience greater levels of sexual desire and interest when fertile (Arslan et al. 2017; Jones et al. 2018a), but it remains unclear if shifts in mate preference also track with menstrual phase. Recent work has failed to find evidence in support of cycle shifts in preferences for masculine faces, bodies, and behavioral displays (Jones et al. 2018b; Jünger et al. 2018b) as well as for masculine voices (Junger et al. 2018).

Further inconsistencies in the literature are reflected in the results of two meta-analyses that reached opposite conclusions about whether women's judgments of men's attractiveness track with changes in women's cycle phase (Gildersleeve et al. 2014; Wood et al. 2014). On the one hand, Wood et al. (2014) reported little support, and on the other hand, Gildersleeve et al. (2014) concluded that cycle effects are robust and influence women's judgments of men's attractiveness in a systematic way. Critically, Wood et al. coded multiple studies for which effect sizes were unknown as "0.00" rather than as missing data, thereby categorizing them as potentially "null effects" and ultimately biasing the estimated overall effect toward zero. Gildersleeve et al. employed multilevel models to account for the nested nature of effects and aggregated across male traits in overall analyses. Differences in the statistical approaches for each meta-analysis may thus have contributed to the uniquely different conclusions.

To evaluate this ongoing question regarding cycle shifts in women's preferences for masculine features, a recent study employed masculine voices as the stimuli of interest in two large within-subjects experiments from different labs, using natural as well as manipulated voice recordings as stimuli, and also examined hormone concentrations and possible moderator variables (Junger et al. 2018). The results failed to support

cycle shifts in women's preferences for masculine voices.

Critically, while some researchers in this line of research argue that null results for cyclic shifts in mate preferences are likely specific to face preferences, this evidence as well as other recent studies evaluating cycle shifts for body or behavior preferences (Junger et al. 2018; Jünger et al. 2018a, b; Marcinkowska et al. 2016) indicate that it no longer appears to be the case that null results are peculiar to face preferences (Jones et al. 2018b; Muñoz-Reyes et al. 2014; Peters et al. 2009). Therefore, there is a strong need for continued work to elucidate the role (if any) of hormonal influences on cycle shifts in women's preferences across categories of stimuli (e.g., voices, faces, bodies).

Cognitively, several lines of research suggest that women in committed and satisfied relationships reportedly have poorer memory for attractive men's faces than women in low-commitment relationships (Wang et al. 2016; Watkins et al. 2017), presumably in the service of maintaining their current relationship by devaluing potential alternatives. Notably, however, partnered women were not significantly different from unpartnered women in memory for attractive male faces in the Wang et al. (2016) study. In a related study evaluating recognition memory for more and less attractive versions of male and female identities, Watkins et al. 2017 found that women in better quality relationships had greater false memories for attractive men. These findings suggest that women's memory for facial cues may vary systematically according to the factors that influence female mating competition and relationship maintenance (i.e., relationship status and male attractiveness).

Strategies to Optimize Mating and Reproduction

Female mate choice is a behavior that systematically biases a female's probability of mating with males having particular characteristics. Thus, female mate choice occurs when females exhibit behaviors such as selectively moving toward

and/or maintaining proximity to certain males, selectively soliciting copulation or attention from certain males, or selectively cooperating with certain males' solicitations, if these behaviors influence the probability of mating with these males (Puts 2010). Thus, differential acceptance of – or resistance to – male attempts at copulation appears to represent at least one form of female mate choice.

Evolutionary theories suggest that men and women are evolutionarily designed to solve different mating-related strategies (Trivers 1972), which lead to differences in mate preferences and competition. Such differences in mate preferences and competition are explained, at least in part, by sexual selection theory. Specifically, due to the relative asymmetry in parental investment between men and women, heterosexual women should theoretically compete with other women for mates that provide resources, while heterosexual men should compete with other men for mates that appear attractive, fertile, and healthy (Buss 1989; Conroy-Beam et al. 2015; Trivers 1972).

Women tend to compete with other women for mates by advertising qualities that are valued by men (e.g., beauty, clothing choice, and sexual exclusiveness; Durante et al. 2008) and by derogating rivals (e.g., through gossip and devaluing other women; Fisher 2004) rather than via direct displays of dominance, as in men. In addition, women tend to be influenced more by peer evaluations (i.e., from other women) than men are (Graziano et al. 1993), suggesting that intrasexual competition in women may elicit a uniquely different dynamic among women than intrasexual competition in men. Men tend to value those physical features in women that are related to *fertility* and *fecundability*, such as youthfulness, vitality, and an ideal body-shape (Conroy-Beam et al. 2015). In addition, when asked to spontaneously mention relevant characteristics about a rival that might attract their partner, women tend to report more jealousy when a rival is high in physical attractiveness (Dijkstra and Buunk 2002).

In most mammals, including primates (Nadler et al. 1983), female sexual activity is heightened during the fertile period of the reproductive cycle (Thornhill and Gangestad 2015). In contrast,

women's frequency of intercourse varies inconsistently (if at all) across the ovulatory cycle (Arslan et al. 2017). Nevertheless, there is a fertile phase increase in sexual motivation and desire, such that women report more in-pair and extra-pair desire as well as self-perceived desirability (Arslan et al. 2017). In addition, women have also reported more flirtation (Haselton and Gangestad 2006) as well as feeling less close to and more critical of their primary partner, particularly if the partner is less sexually attractive (Larson et al. 2013).

In short, women's sexual behavior and libido both appear to shift across the cycle, and evidence suggests that this shift tracks with ovarian hormones (for review, see Motta-Mena and Puts 2017). This raises intriguing questions about evolutionary causes and hints at roles of pair-bonding and extra-pair mating. If ovulation is concealed and copulation occurs throughout the cycle, then a mid-cycle rise in libido could promote extra-pair copulation in order to recruit good genes, while also being able to retain non-genetic benefits conferred by the pair-bond partner (Thornhill and Gangestad 2015). Ultimately, however, more work is necessary to evaluate and understand how women's sexual behavior throughout the cycle has evolved to produce adaptive outcomes.

Conclusion

Using a life history approach, this entry highlights the unique nature of women's mating behavior and cognition from puberty to young adulthood. While a clearer picture is emerging, many questions remain regarding how women select their mates throughout the lifespan, and particularly how they select and maintain long-term partners. While more fieldwork is ultimately necessary to understand the magnitude of effects outside of the laboratory in more naturalistic settings, recent work employing hormonal assays (Junger et al. 2018; Kordsmeyer et al. 2018; Shirazi et al. 2018a), large datasets with behavioral recordings (Arslan et al. 2017), as well as international samples (Shirazi et al. 2018b) provide robust evidence

and methodological rigor for elucidating women's mating behavior.

Definition

Occlusion is a monocular depth cue produced by partially overlapping objects: Objects that partially block other parts of the scene are perceived to be closer to an observer than the blocked objects.

Introduction

Like motion parallax, occlusion is a monocular depth cue that does not require integrating information from two retinas. Unlike motion parallax, however, occlusion is a pictorial depth cue that is available in static images. In addition to using occlusion for ordering objects in depth, human observers have a strong tendency to perceive partially occluded objects as being completed behind an occluded surface, a process called *visual completion* or *amodal completion*. However, the presence of amodal completion in non-

primate species is less explored and, in some cases, controversial.

Occlusion and Visual Completion in Humans and Nonhuman Animals

All organisms inhabit a world filled with opaque objects; thus, their visual systems must constantly deal with recognizing these objects on the basis of their visible parts and ordering them in depth. Human visual system handles these tasks by automatically completing partially occluded objects (Fig. 1); at 7 month of age, infants show both the ability to use occlusion for ordering objects in depth and to amodally complete them (Kavsek 2004).

In humans, amodal completion is normally demonstrated by using two-dimensional images similar to those shown in Fig. 1. The observers are asked, either directly or indirectly, to judge whether the occluded image (e.g., a rectangle, Fig. 1a) is more similar to the completed version of that image (e.g., a full rectangle, Fig. 1b) or an incomplete version that presents the portions not obscured by the occluded (Fig. 1c). Although this

Occlusion, Fig. 1 An illustration of amodal completion. When shown an image with overlapping objects (a), human observers assume that it consists of complete objects (b) rather than their visible parts (c)

approach has successfully been used for a number of mammalian species (reviewed by Fujita 2006), many other efforts to demonstrate amodal completion using such images were either unsuccessful (pigeons: Sekuler et al. 1996) or required additional contextual cues or experimental manipulations to induce amodal completion (baboons, Deruelle et al. 2000; pigeons, Nagasaka et al. 2007).

In contrast, experiments using real three-dimensional objects consistently revealed amodal completion in a variety of species (fish, Sovrano and Bisazza 2008; baboons, Deruelle et al. 2000). Moreover, pigeons have recently been shown to use occlusion for ordering two-dimensional objects in depth (Cavoto and Cook 2006), further suggesting that they may be capable of amodally completing objects in certain circumstances.

On the other hand, pigeons have also been shown to experience difficulties in recognizing pictures of occluded objects without additional experimental manipulations (Aust and Huber 2006; Lazareva et al. 2007). It is therefore possible that their depth perception in two-dimensional images is generally impaired unless motion-induced cues such as motion parallax are available. Unfortunately, there are no current studies exploring pigeons' (or any other bird species) amodal completion with static three-dimensional objects; thus, the conclusions about the generality of monocular depth cues in avian vision must await further comparative research. Finally, there is no current evidence to suggest that insects or other invertebrates either recognize partially occluded objects or amodally complete them (Baum et al. 2014).

Conclusion

Human observers experience little difficulty in navigating the world filled with partially occluded objects, possibly due to their ability to spontaneously perceive partially occluded surfaces as complete. Although animals must undoubtedly face the same problems, the evidence for the ability of vertebrate animals to recognize partially occluded objects and to amodally complete them

remains mixed; it is currently unknown whether invertebrates employ amodal completion or use occlusion as a depth cue.

Definition

The improvement through experience of the ability to detect and or/discriminate sensory stimuli.

Introduction

It is widely believed that the sense of smell has minimal impact on the critical aspects of existence. However, research has shown that olfaction is deeply involved in every aspect of our lives. Of all the forms of odor memory, odor recognition is the most common and direct measure of odor memory (Crowder et al. [1995](#)). Odor-evoked

memory is responsible for providing us a sense of self, who we are, where we are in time and place, present and past (Herz [2011](#)). The anatomy of olfaction seems to be tied to our emotions, motivations, and associations in a unique way which provides us with our personal and interpersonal experiences.

What Is Odor-Evoked Memory?

Odor memory is used to define both memory of odors and memory evoked by odors (Herz and Engen [1996](#)). Research in this field begun early in the twentieth century when early investigators compared verbal associations using images and odors as cues and found that odors were weaker reminders than images, described the emotions and associations odors evoked, and also described the characteristics of odor-evoked memories (Bolger and Titchener [1907](#); Kenneth [1927](#); Laird [1935](#)). Over the past decades, modern experimental methods have been used to investigate olfactory memory using cognitive experimentation such as the role of verbal mediation in olfactory processing, the duration of memory, olfactory recall and imagery, and neurological techniques that focused on impaired versus spared dissociation in clinical populations (Pelosi [1994](#)).

Most odors experienced in nature are a combination of many different odorant molecules. The ability to discriminate between these odors is one of the main functions of olfaction. This process involves initial analysis of the inhaled stimulus into its component molecular features which are then combined to provide a unitary odor object such as “chocolate” (Wilson et al. [2009](#)). The more familiar the odors become the more enhanced the encoding of the feature and their synthesis into objects becomes as well. This process leads to improvements in sensory discrimination in other words to determine whether two stimuli are different or the same. However, the ability to remember odors and the experience of memory evoked by an odor are two distinct cognitive-perceptual processes. Remembering odors refers to the ability to identify that you have smelled a specific smell before, and it does

not bring back any particular memory event (Herz 2011). On the contrary, memory evoked by an odor refers to the ability to recollect a specific event from one's life, but it does not have much to do with the odor itself. There is a possibility for the two processes to overlap in certain situations.

In the last 20 years, research concerning the special attributes of odor-evoked memory has been widely conducted. Herz et al. (2004) found left hemisphere dominance during episodic odor-evoked recall. Rubin et al. (1984) compared odor memories of participants with memories evoked by photographs or names and found that memories evoked by odors were reported as never having talked about prior to the experiments. They also suggested that odors might evoke more pleasant and emotional memories compare to other stimuli (Rubin et al. 1984). Hinton and Henley (1993) conducted a study to compare responses to stimuli that were resented in visual, lexical, and olfactory modalities. Their results indicated that the olfactory mode is significantly more emotionally arousing than verbal or visual stimuli and that odors can be more personally involving than those elicited by other sensory stimuli (Hinton and Henley 1993). However, odor-evoked memories do not elicit more accurate memories than other sensory cues (Hertz and Cupchik 1992). Research that followed suggested that memories triggered by olfactory information differ compared to memories evoked by verbal and visual information (Herz and Schooler 2002; Willander and Larsson 2006) in that they are more emotional. The results of Willander and Larson (2007) in their study of 72 older adults indicated that semantic knowledge of an odor's name significantly affects the age distribution of memories such that the memory peak in childhood observed for odors only was attenuated.

Characteristics of Odor-Evoked Memory

In order for an odor to be remembered, it needs to be encoded and stored in the olfactory system. This process is regulated by neuromodulators which store information in a way that maintains

the olfactory experience significant (Wilson and Stevenson 2006). The neurotransmitters nor-epinephrine and acetylcholine that affect both the implicit and explicit memory regulate these systems. Implicit odor memories do not require the deliberate recollection of an odor experience in order to form in the brain (Rouby et al. 2002). Previous exposure to a familiar stimulus seems to help the formation of implicit memories (de Wijk et al. 1995) through the process of habituation due to prolonged exposure to a stimulus (Wilson and Stevenson 2006). Jonesgotman and Zatorre (1993) studied odor memory in 121 patients with unilateral cerebral excision from temporal, frontal, frontotemporal, or centroparietal areas, and in 20 control subjects and found that participants showed impairment only after excision from the right temporal or right orbitofrontal cortex. All groups showed significant forgetting over time, and verbalized odors were recognized more efficiently than unlabeled ones. Rasch et al. (2007) in their study cued new memories in humans during sleep. They presented an odor that had been presented as context during prior learning. Their results showed that reactivation indeed causes memory consolidation during sleep and that reexposure to the odor during slow-wave sleep (SWS) improved the retention of hippocampus-dependent declarative memories but not of hippocampus-independent procedural memories. On the contrary explicit odor memories refer to memories that are consciously remembered, which in terms of olfaction refers to attribution of associative meaning to a specific odor (Radvansky 2006; Wilson and Stevenson 2006). By associating meaning to odors information is stored in a way that will aid in processing and comparing to other odors (Wilson and Stevenson 2006). Odor recognition and odor identification are probably the most commonly used tests to measure odor memory (de Wijk et al. 1995).

Several characteristics of odor-evoked memories contribute in distinguishing them from memories evoked by stimuli perceived through other sensory modalities (Herz 2011; Larsson et al. 2014). The most distinctive characteristic of these memories is their ability to evoke more emotional and evocative recollections than any

other stimuli (Herz 2016). This is due to the neuroanatomy of the olfactory cortex which includes the amygdala, the part of the brain that processes emotional experience and emotional memory as well as the hippocampus, which is responsible for associative learning (Aggleton and Mishkin 1986; Cahill et al. 1995; Eichenbaum 2001). The amygdala is a complex set of nuclei involved in the formation of memories of emotional experiences associated with defense, flight, and fear. The direct projections from the amygdala to the hippocampus involve integration of various sensations into memory which is extremely important for the development of olfactory memories (Buchanan et al. 2003). The olfactory system is the only one that makes direct and intense contact with neural substrates of emotion and memory, which may provide a better understanding of why odor-evoked memories are usually emotionally potent. Other sensory modalities are mediated by limbic projections which are connected to associational areas (Herz and Engen 1996).

Another unique characteristic of the olfactory system that is directly associated to odor memory is the fact that incoming information is not processed in the thalamus before it is projected directly to the cerebral cortex, it occurs in the primary olfactory cortex (Carmichael et al. 1994). Neural transduction in the olfactory system seems to be different than any other sensory modalities. The neurons are unmyelinated, thereby assisting the sensation of an odor to remain for a greater period of time than other sensations. These unique interconnections are responsible for the emotionally evoked memories.

Context-Dependent Memory

Based on the principle that environmental features encoded as part of a memory trace can contribute to memory for stored odors, context-dependent memory is formed. In other words, odors facilitate the retrieval of information already learned (Schab 1990; Smith et al. 1992). Ehrlichman and Halpern (1988) found that participants recalled significantly more positive memories

when presented with a pleasant odor than when they were presented with an unpleasant odor. Herz and Engen (1996) note that hedonic and emotional responses that maybe elicited from an odor depend on how the odor was first encountered. Hence, they seem to be based on learning principles.

It has been demonstrated in studies that hedonic and emotional responses an odor elicits are dependent on how the odor was first encountered. Jellinek (2004) notes that awareness of the emotions associated with an olfactory experience is prior to awareness of the presence of the sensory stimulus which elicits the experience. Almost all responses of odors have been shown to be based on associative learning principles (Davis and Ludvigson 1995). Therefore, if an odor is perceived as pleasant, it was first experienced in a pleasant context.

Herz and Cupchik (1992) proposed a theory based on the primacy of associative mechanisms in olfactory learning in order to explain autobiographical odor-evoked memories. He stated that if an odor is first experienced in an emotionally salient context, it will become a very effective trigger for the recollection of this memory. This is due to the higher level of activation in the amygdala which is critical for emotional memory (Cahill et al. 1995).

To examine the relationship between odor and emotion studies investigated whether heightened emotional states during the encoding of information relating to a new odor enhance the retrieval of that odor. The results indicated that word recall was higher when a specific odor was present at encoding and retrieval compare to no odor cue being available (Herz and Engen 1996). These findings support the theory that emotion is a vital variable in the formation of autobiographical odors.

Conclusion

Many studies have proved the existence of long-term odor memory and of previous experiences triggered by odors. Odors that are associated with emotion arousing events tend to be remembered

for years maybe even throughout the life span. The available data from various studies suggest that memories evoked by odors have several distinct characteristics related to their emotional quality such the fact that memories elicited by odors seem to be more emotionally potent than memories triggered by other sensory stimuli, and it seems this saliency produces the impression that odor memories are more real. Neuroanatomical evidence is consistent with this finding (Herz and Engen 1996).

Definition

Protecting progeny against threats that may cause resource loss, bodily harm, or death

Introduction

In most species, the risk of extrinsic mortality (mortality due to external forces such as predation) is much higher for young than it is for adults. Young organisms are generally slower, smaller, and, due to inexperience, less skilled at navigating the world around them than adults are. While this is the case for nearly all species, it is particularly true for species which have altricial (as opposed to precocial) young. This includes humans, whose infants are considerably less neurologically and behaviorally developed at birth than the neonates of most other primates (Freedman 2016). They are entirely reliant on older caretakers for all of their basic needs, including protection.

In many species, there is considerable selective pressure on one or both parents to protect their offspring from threats of all kinds. By the time any young organism comes into the world, its parents have spent considerable energy getting it there. Both males and females have invested in gamete production and mating. For eutherian mammals, females have invested in internal gestation, and for all mammals, mothers continue using energy to lactate throughout their offsprings' infancy (Trivers 1972). In many birds and some fish, reptiles, amphibians, and invertebrates, both females

and/or males may have spent time incubating or guarding eggs (Clutton-Brock 1991). These investments in their direct fitness will only pay off if parents can keep their offspring alive long enough for them to reproduce.

While defense of young may come from a variety of sources, especially in highly social species such as humans, this entry is concerned specifically with offspring defense, that is, parents defending their young. In most cases, this means genetic parents, though depending on the specifics of the biological system, young may occasionally be raised by “social parents” who are not biologically related (e.g., human families with adopted children).

Defense Across Development

Depending on the ecology and life history of the species under consideration, offspring defense may take place within a small discrete window or continue across multiple stages of development. Some forms of defense begin at the moment of conception. For mammals, internal gestation provides the fetus with a considerable buffer against the outside world. While mothers are therefore a fetus’ first line of defense, in social species, a fetus can indirectly benefit from protection provided to its mothers by other group members, including the fetus’ father. In species that do not gestate internally, parents may protect vulnerable eggs from hungry predators by depositing them in places where they are hard to detect (e.g., Marquardt et al. 2016) or guarding their nests directly (e.g., Komdeur and Kats 1999). Some species that hide eggs leave immediately afterwards; their offspring defense begins and ends with finding a safe place for eggs to incubate. Others abandon offspring defense as soon as their progeny emerge (e.g., some nest-guarding reptiles; Gans 1996). After offspring hatch or are born, defense may occur in a variety of forms from infancy through early adulthood. In species with slow life histories such as primates (including humans) and cetaceans, offspring defense may continue over the course of many years (Clutton-Brock 1991, 2016).

Various models have been proposed to explain changes in parental defense behavior across offspring developmental stages. All fall within the basic theoretical framework of parental investment theory (Trivers 1972) and its associated cost/benefit analysis of the returns to various behavioral strategies (Montgomerie and Weatherhead 1988). One hypothesis is that parents will more vigorously defend offspring as their expected reproductive returns get closer to that of their parents (i.e., as they get closer to the end of the high-mortality infancy and/or juvenile period). Another proposes that parents will most vigorously defend infants who are most vulnerable to a given threat. Defense intensity or type may also vary as a function of offspring quality or number, parental experience, the confidence parents have that offspring are theirs, and/or the relative formidability of the threat, among other variables (reviewed in Montgomerie and Weatherhead 1988). The majority of empirical work testing such hypotheses has occurred in birds (but see also Koskela et al. 2000; e.g., Mahr et al. 2015; Thünken et al. 2010). However, there is little theoretical reason to believe that the underlying hypotheses are not equally applicable to most taxa, including humans.

What Do Parents Defend Offspring Against?

Predation: Most young organisms require protection from predation, which is a major source of extrinsic mortality in many species (Caro 2005). For many, parents’ deterrence and defense are the first and only form of protection against daunting odds. Even among apex predators (e.g., leopards, wolves) and species with adaptations (e.g., large body size) that make them functionally immune from predation in adulthood, predation is a meaningful risk during infancy. On land, young may be vulnerable to myriad terrestrial carnivores and omnivores, including felids, canids, snakes, raptors, and predatory arthropods. In the water, young animals have to contend with an equally daunting array of predatory fish, reptiles, amphibians, mammals, and even birds. Some social

species have sophisticated predator detection and warning systems that may benefit many social group members, including offspring (e.g., vervet monkeys: Seyfarth et al. 1980). Though many humans today do not incur any meaningful risk of predation, throughout humans' evolutionary history, predators – particularly large cats and caniform carnivores such as wolves – were likely an important threat to humans and their ancestors (Barrett 2015). Just as is true for other species, young humans were (and still are, in places where large predators remain in the ecosystem) likely an especially attractive target for predators.

Infanticide: In mammal species where the length of lactation exceeds the length of gestation, sexually selected infanticide (performed by males seeking mating opportunities with an infant's mother) is a common cause of infant mortality (Hrdy 1979). Defending offspring against infanticide may be an important driver of long-term male-female associations, since continual male presence means males not only have the ability to guard infants throughout development but also have higher paternity certainty, which incentivizes incurring the costs associated with infant protection (Palombit 2000). In many mammal species where infanticide is common, infanticide defense is likely the most evolutionarily consequential type of paternal care that fathers provide their offspring. Males' simple presence may be enough to deter many potentially infanticidal intruders, though they may also be forced to directly fight off threatening outside males (Palombit et al. 2000).

While males may be important infant defenders in some species, females have also evolved various counter strategies to mitigate infanticide risk. Depending on the specifics of the biological system, these may include grouping together to collectively defend against males; speeding up the weaning process, since infants that are still nursing are at far greater risk than infants who are weaned; changing behavioral patterns to avoid potentially infanticidal males; and deliberately sowing "paternity confusion" among multiple potential sires (Palombit 2012). These may all be viewed as forms of offspring defense.

Infanticide committed *by* females is far less common, though is well documented in certain taxa including mice, mongooses, and some social insects (Parmigiani and vom Saal 2016). Females may commit infanticide to curtail resource competition (e.g., food, paternal, or alloparental care) for their own offspring, or for the nutritive benefits, when it is accompanied by cannibalism. Unsurprisingly, in species where female infanticide is common, females also appear to have evolved behavioral or reproductive strategies to mitigate the risk other adult females pose to their offspring. These include territoriality, where females aggressively exclude others from the area(s) where they are raising their young (Wolff and Peterson 1998), and in species that breed communally, timing reproduction so that infants are less likely to be killed by allomaternal caretakers (Schmidt et al. 2015).

There is substantial evidence in the academic literature that patterns of infanticide in modern human populations meet predictions derived from an evolutionary framework. Young children are more likely to be abused or killed by step-parents than by biological parents, and when biological parents commit infanticide, it appears to be more often driven by instrumental concerns such as resource instability or offspring phenotypic quality (reviewed in Archer 2013). While absolute risk of infanticide is quite low in humans, parental presence may nonetheless be a form of offspring defense against infanticide as well as other threats.

Conspecific harassment: Finally, infants may also require defense against conspecific harassment. Both older animals and age mates may harass or bully infants, and parents can play an important role in defending them (Nguyen et al. 2009). Harassment can lead to injury, lack of access to prime resources, and considerable energy spent on self-defense, all of which are detrimental to a young organism's growth and development.

How Do Parents Defend Offspring?

Fighting: Depending on the relative size and formidability of an opponent, be it a predator or a

conspecific, parents may respond by threatening or directly attacking. Among social animals, group members will sometimes mob predators, which has protective advantages for all group members, including offspring. Direct attacks can carry considerable risk, as parents themselves may sustain injuries or be killed in the course of protecting their offspring (Alcock 2009).

Fleeing: When opponents are too large, formidable, or numerous to effectively fight off, parents may flee with their offspring. This tactic is most feasible in species that give birth to one offspring at a time (monotocous species), especially those that have physically precocial young. For example, young ungulates (hooved mammals) are able to run within a few hours of birth, an adaptation that is clearly beneficial to large herbivorous species which are vulnerable to multiple types of predators. Fleeing is far harder, or even impossible, in species that give birth to litters of young or in which infants must be carried. Carrying an infant may considerably slow down the carrier and thus increase the risk of injury or death for the parent(s). However, phylogenetic analyses suggest that carrying infants, rather than hiding them, decreases the risk of infant mortality in primates (Ross 2001). Thus, this appears to be a superior offspring defense strategy in some species.

Cryptic strategies: Some prey species rely heavily on stealth tactics, to avoid predator detection in the first place. For example, in cotton-top tamarins (a small-bodied species of New World monkey), adults carrying infants move less and spend more time concealed, perhaps to decrease their risk of predation for both adult and infant (Price 1992). While this is a useful strategy in species in which infants are regularly carried, the energetic costs of doing so are considerable. Not only is infant carrying itself metabolically expensive, it is also likely to hamper forging or hunting efforts (Price 1992). Unsurprisingly, then, there are many species in which females “park” or hide infants somewhere safe while they feed (Tecot et al. 2012).

Territoriality: While there are many reasons that animals, including humans, defend territories,

one may be to protect offspring (Hinsch and Komdeur 2017; Wolff and Peterson 1998). Owners may guard their territories against conspecifics or predators who threaten their offspring or important resources that their offspring need (e.g., food). Territoriality is a particularly useful offspring defense strategy when young are hard to transport and thus constantly directly guard. This may occur because there are too many of them to feasibly move, because morphological constraints prevent transport (e.g., an adult deer cannot carry its fawn) and/or because altricial characteristics prevent offspring themselves from moving about with their parents (Wolff and Peterson 1998).

Social learning: Human parents often teach children very early about how to spot dangers of all kinds and defend themselves against them. Active teaching about risk-mitigating behaviors constitutes a very important form of offspring defense in humans. Cross-cultural data suggest that humans have evolved a “danger learning system” that relies on multiple sensory cues to obtain and retain important information about sources of risk in the environment (Barrett 2015; Barrett and Broesch 2012). While this learning system is not parent-offspring specific, parents are a crucial source of information for their offspring, since they are important social partners who are often in close proximity. Of course, humans are not alone in their propensity for social learning. The young of most, if not all other, social species also use social cues to learn about dangers in their environment (Crane and Ferrari 2013). Just as for humans, nonhuman animal parent(s) may be a frequent source of social information, which is an important contribution to their offspring’s safety.

Technological and social innovations: In addition to the “fight-or-flight” responses employed by most animals, human innovations such as controlled use of fire, dog domestication, and sophisticated building practices (e.g., fences, alarm systems, and sturdy dwellings) serve as threat deterrence devices that allow parents to defend their offspring even while not physically present. In addition to such innovations, humans also use a wide variety of social institutions,

including law enforcement, courts, military, and social services, to help mitigate the need for individual direct protection under typical social conditions.

While such adaptations clearly occur in their most elaborate form in humans, many other vertebrates and invertebrates also build nests, dens, or burrows that protect their offspring (Alcock 2009; Clutton-Brock 1991). Other species also may employ innovative defensive techniques that do not slot neatly into fight-or-flight categories. For example, there is intriguing evidence that in species which use chemical defenses against predators, mothers may actively provision their offspring with the compounds needed to do so (Stynoski et al. 2014). Among birds, “broken wing displays,” where a parent feigns injury in order to lure an intruder away from their eggs or chicks, are a common form of offspring defense (Caro 2005). Most biological systems, especially invertebrates, are quite understudied relative to humans, with means that other species may have evolved additional forms of offspring defense that have yet to be described in the scientific literature.

Conclusion

Offspring defense is an important component of parental investment in many taxa. It can take diverse forms, including: direct defense either of offspring, or of territory and resources that they use; helping offspring to hide or flee from danger; providing them with information about danger and how to avoid it; and making use of technological or social innovations that provide protection. Offspring may face many different threats across the course of development, including but not limited to predation, infanticide, and conspecific harassment. While modern human societies have created myriad social institutions and technologies that dramatically reduce the need for routine direct offspring defense, parental defense of young was likely an important selective force in the evolutionary history of humans and their ancestors.

Offspring Diversity Hypothesis

Katherine Starkweather

Anthropology Leipzig, Germany

Synonyms

Genetic diversity hypothesis

Definition

Females mix sperm from different males in order to increase the genetic diversity of their offspring.

Introduction

If polyandry is a female strategy, it must benefit the reproductive success of females. By mating with more than one male, females may enhance

their fitness through direct or material benefit, such as increased provisioning. The payoff to fitness may also be genetically based. One possible explanation for these genetic benefits is the *offspring diversity hypothesis*, which states that females mix sperm from different males in order to increase the genetic diversity of their offspring (Williams 1975). Sexually reproducing parents produce genetically variable offspring because recombination of male and female genes produces novel gene combinations (Williams 1975). Genetic contributions from multiple males will result in more novel gene combinations and even greater offspring genetic diversity. Such diversity can improve female fitness either by reducing sibling competition or by serving as a hedge against environmental uncertainty (Loman et al. 1988; Watson 1991). Watson (1991) suggests that females who are employing this strategy should (1) have low quality of information on male viability and (2) choose to mate with the most phenotypically unique males, regardless of their viability.

Benefits of Offspring Diversity

In some species, more genetic diversity in a sibling set decreases between-sibling competition for resources and increases offspring survival (e.g., Aguirre and Marshall 2011). If genetic variation among offspring results in differences in morphology, physiology, or behavior, then genetic variation may also lead to variation in resource use, thus reducing competition for the same resources between members of the same clutch (Case and Taper 1986). Genetically diverse offspring may also result in increased fitness for their mother in unpredictable environments (Yasui 2001). Phenotypic differences will cause offspring to respond with variable success to changes in the environment, and a more diverse brood will increase the chance of at least some offspring surviving. Genetic and phenotypic diversity is less favorable in stable environments, however, which favor broods with the maximum number of individuals fit to the current environment (Yasui 2001).

Offspring Diversity Mechanisms

Some nonhuman females can obtain a diverse sperm pool by mating with multiple males within a short period of time, resulting in those males fertilizing the same clutch (e.g., Ridley 1993; Watson 1991). Other females – nonhuman and human – can also increase genetic diversity in offspring by mating with different males at longer intervals, resulting in subsequent pregnancies of which different males sire individual or clutches of offspring (Jennions and Petrie 2000). Humans achieve multiple mating in one of three ways: divorce and remarriage, extra-pair mating, or polyandry. The relationships between the men and women mate within subsequent marriages or extra-marital affairs have not been studied. However, we know it is very common for men in polyandrous relationships to be closely related to one another and for primary husbands to play a role in deciding who the subsequent husbands will be (Starkweather and Hames 2012). When a woman's multiple mates are brothers or first cousins, it is unlikely that her offspring will be very genetically diverse.

Conclusion

Evidence in support of the offspring diversity hypothesis is difficult to achieve for all animals, but particularly for humans given ethical constraints (Scelza 2013). So far, no studies have compared the genetic quality of in-pair and extra-pair offspring among humans. Some studies are using proxy measures for quality, such as facial symmetry and major histocompatibility complex (MHC) compatibility, in order to determine if and when these traits are preferred by women. Higher MHC similarity between partners indicates genetic incompatibility, and women report more extra-pair desires and mating when they have greater MHC similarity with their long-term partner (Garver-Apgar et al. 2006). A true test of the offspring diversity hypothesis does not yet exist, however, and would entail comparing the genetic diversity within sibling sets and determining the effect of stable versus unpredictable

environments. Given the nature of the husbands' relationships to one another in most polyandrous, it is unlikely that tests of the offspring diversity hypothesis would find support within polyandrous unions.

Chromosomal composition of an individual's progeny

Introduction

Offspring sex refers to the chromosomal composition of an individual's progeny. In humans and most other mammals, this is determined by the joint contribution of either an X- or a Y -chromosome-bearing sperm from a father and the X chromosome-bearing ovum from a mother. Males possess both an X and a Y chromosome, whereas females possess two X chromosomes. Offspring sex can be influenced both pre- and postconception, and this is affected by many biological and environmental factors. Evolutionary theory predicts that parents may be able to adjust the sexes of their offspring. Although the exact mechanism for this remains unknown, several

physiological, psychological, and environmental factors have been implicated.

Facultative Adjustment of Offspring Sex

Sex ratio, or the ratio of the number of males to the number of females within a population, can be considered at both primary and secondary levels (tertiary sex ratio, or number of males to the number of females at sexual maturity in a population will not be discussed here). Primary sex ratio refers to the sex ratio at conception and secondary sex ratio refers to the sex ratio at birth. Although in humans the secondary sex ratio remains relatively stable at approximately 105–107 male births for every 100 female births, the primary sex ratio is more difficult to quantify.

Deviations from the typical male-biased secondary sex ratio have been observed in response to various large-scale events (e.g., wars) (reviewed in James 2009), but it was not until the Trivers-Willard hypothesis (Trivers and Willard 1973) was published that researchers began to untangle the potential mechanisms through which these changes might occur. Since then, parental manipulation of offspring sex has been studied from physiological, psychological, and environmental contexts, both pre- and postconception. However, in meta-analyses with ungulates and primates, respectively, both Sheldon and West (2004) and Cameron (2004) have demonstrated that facultative adjustment of offspring sex is most likely to occur close to conception rather than as a result of differential investment in offspring postconception. Thus, adjustment of sex ratios at conception may be the source of skewed secondary ratios in response to factors associated with the maternal environment.

The bulk of research involving facultative adjustment of offspring sex preconception involves maternal influences. Three physiological mechanisms have been proposed: stress, glucose availability, and testosterone levels (reviewed in Edwards et al. 2016). Maternal stress increases endogenous concentrations of glucocorticoids (e.g., cortisol), which may explain female-biased

sex ratios in chronically stressed women. Maternal glucose availability, which is indicative of energy store, is positively associated with the frequency of male offspring. Similarly, maternal testosterone levels may also increase the probability of conceiving a male (Grant et al. 2011). Paternal influences on offspring sex, such as changes in the proportions of X- and Y chromosome-bearing sperm in seminal fluid, may also occur, but this has not consistently demonstrated.

Interestingly, maternal stress, glucose availability, and testosterone level may all be interrelated and under the influence of psychological mechanisms. Maternal dominance, or a combination of inherent female traits (e.g., influential, authoritative), that facilitate the changing of another's view or actions, for example, has been associated with the production of male offspring in women (e.g., Grant 1990, 1994). It may also be associated with better access to resources (and thus, sources of glucose) and lowered feelings of stress, ultimately producing an intrauterine environment conducive to the conception of male offspring. Indeed, larger women as well as women with greater muscle mass in the upper arm – a possible proxy for nutritional status (i.e., resource acquisition ability) – also have more sons (Kanazawa 2005; Gibson and Mace 2003).

Conclusion

Offspring sex refers to whether an individual's progeny is chromosomally male (i.e., XY) or female (i.e., XX). Although offspring sex can be determined at both primary (i.e., at conception) and secondary (i.e., at birth) levels, the majority of human research involves analysis of the secondary sex ratio. Facultative adjustment of offspring sex has been proposed and likely takes place at conception under the combined influence of both physiological and behavioral influences.

evolution as maintaining proximity to caregivers was associated with increased chances of survival and thus reproduction. Accordingly, children come into the world prepared to form attachments, doing so to individuals who are sufficiently available and responding to children's attachment behaviors. Offspring–parent attachment therefore denotes a hierarchical bond between children (the smaller and weaker part) and their caregiver(s) (the stronger and wiser part) and not the emotional bond that caregivers form to their offspring. Attachment bonds take time to form and are typically observable during the second half of children's first year of life, when attachment-related experiences with the caregiver(s) have become internalized in the child in the form of cognitive-affective representations of self and others (internal working models, [IWMs]) that organize the child's behavior and displays of affect in relation to the caregiver(s). Offspring–parent attachment varies in quality or organization depending on the caregiver's pattern of responding to the child's signals and is typically described using two dimensions (secure/insecure, organized/disorganized) subsuming four categories (secure, insecure-avoidant, insecure-resistant/ambivalent, insecure-disorganized/disoriented).

Introduction

Universally, human infants form strong bonds – attachments – to caregiver(s), seeking to maintain proximity to and protesting separations from the caregiver(s) and using the caregiver(s) as a “secure base” from which to explore the environment and a “safe haven” to return to for comfort and protection when distressed. John Bowlby, a psychoanalyst and child psychiatrist (see ► [“John Bowlby: Pioneer of Attachment Theory”](#)), was unsatisfied with the available explanations of attachment, with psychoanalytical and social learning theories deeming attachment a secondary result of children's drives and feeding (see ► [“Psychodynamic Foundations”](#)). Bowlby contested these “secondary drive theories,” arguing that attachment is a primary motivation, and sought an alternative explanation. He came to

Offspring–Parent Attachment

Definition

Offspring–parent attachment denotes the strong bonds that children form to their caregiver(s), seeking to maintain proximity to and protesting separations from their caregiver(s) and using the caregiver(s) as a secure base to explore the environment and a safe haven to return to for comfort and protection. Children are endowed with an attachment behavioral system retained in

draw from multiple scientific traditions, most notably ethology and evolutionary theory, cognitive theory, and control systems theory as applied to ethology (see ► [“Evolutionary Foundations of the Attachment System and Its Functions”](#)). The phenomenon of offspring–parent attachment, or to paraphrase Bowlby, “the nature of children’s ties to their caregivers” (Bowlby 1958/1982), is discussed below (see Cassidy 2008, for a thorough introduction).

The attachment system, attachment behaviors, and the relation between the attachment system and other behavioral systems. Bowlby (1982), following Darwin (1859), and drawing from ethology, argued that humans (and some other animals) are endowed with an attachment behavioral system that was retained through natural selection as it served an adaptive function in primate species’ typical ancestral environments (see ► [“Evolutionary Foundations of the Attachment System and Its Functions”](#)). Specifically, Bowlby argued that the “predictable outcome” following activation of the attachment behavioral system is proximity to caregivers, which have served a biological “function” of increasing chances of survival against predators and other natural dangers (see ► [“Infant Survival”](#) for a discussion of alternative suggestions, such as facilitating learning from caregivers). As individuals endowed with an attachment behavioral system ultimately had more progeny, the attachment system became a stable characteristic of the human species.

Bowlby argued that the attachment system is interacting with other behavioral systems, most notably the fear system and the exploratory system. Regarding the fear system, Bowlby argued that the attachment system is activated by internal (e.g., illness, pain) and external (loud noises, darkness, strangers, separations from caregivers) signals of threat/danger and similarly terminated by signals that there is no more cause for alarm (as opposed to buildup and discharge of psychic energies, see ► [“Psychodynamic Foundations”](#)). For young infants, close (physical) proximity to the caregiver(s) is often paramount to terminating the activation, whereas older children, who, for example, have acquired language, can be soothed

by more elaborate means, such as talking to the child and conveying that there is no cause for alarm (psychological proximity). The attachment system is, however, also thought to affect the fear system, with children typically more able to explore their environments (i.e., less prone to fear), when a caregiver is available for comfort and protection (i.e., as a “secure base”; see ► [“Individual Variations in Attachment”](#)). Bowlby also argued that humans have an exploratory system (and an innate motivation to explore the environment) and that the attachment and exploratory systems are mutually inhibiting so that when one is activated the other is deactivated. Importantly, Bowlby argued that having a caregiver available as a secure base (or an internalized representation of the caregiver as available, called “felt security”) supports children’s ability to explore the environment (e.g., increasing their epistemic space). Children’s ability to balance flexibly between their attachment needs and need to explore the environment is therefore key in individual variations in attachment (see ► [“Individual Variations in Attachment”](#) for a further description). Moreover, variations in attachment are thought to partly affect children’s further development through effects on children’s ability to explore the environment (see ► [“Effects of Attachment Quality and Organization”](#)).

Children come into the world social and prepared to form attachments to caregivers who are (sufficiently) available and responding to their signals, particularly during times of distress when the attachment system is activated. Children are endowed with attachment behaviors, which are described by their evolutionary function of maintaining/increasing proximity to caregivers. Such behaviors include positive (e.g., vocalizing, smiling) and aversive (e.g., crying, screaming) signal behaviors and active behaviors such as following and clinging, with increased development of motor, language, and cognitive abilities expanding the repertoire of attachment behaviors as children grow older.

Bowlby also argued that caregivers are endowed with a complementary caregiving system, rendering them biased and responsive to their children’s signals, which possibly developed as

parents' genes are only passed on to future generations if their children survive and have progeny of their own (Simpson and Belsky 2008). Caregivers are, for example, usually monitoring their children's whereabouts and retrieving them (increasing proximity) upon cues of danger. Children's forming of attachments to their caregivers is thus a collaborative effort, and since children's environments typically include caregivers who are responding to their signals, almost all children form attachments (called "the universality principle"; van IJzendoorn and Sagi 1999), and the attachment system is hence considered a moderately environmentally stable system (but see ► ["Disorganized Attachment and Reactive Attachment Disorder"](#) for detrimental effects following severe social deprivation). The collaborative process between children and their caregiver(s) does however not mean that caregivers are attached to their children, a common misconception. Attachment denotes the bond that offspring form to their caregivers. That is, the nature of children's ties to their caregiver(s) is a hierarchical relationship between the child (the smaller, weaker part) and the caregiver (the stronger and wiser part), thought to stem from the evolutionary survival value of maintaining proximity to caregivers (see ► ["Attachment in Adulthood,"](#) for differences in functioning in adult relationships). With the words of Bowlby: "Because immature organisms are usually very vulnerable they are commonly endowed with behavioral equipment that produces behaviors specifically likely to minimize risk, e.g., behavior that maintains proximity to a parent" (Bowlby 1997/1982, p. 143).

Development of attachment, attachment representations, and individual variations in attachment. Attachment bonds develop slowly during children's first year of life and are typically first observable around 7–9 months of age, that is, when children are seen to monitor and maintain proximity to the caregiver(s) and to use the caregiver(s) as a "secure base" and a "safe haven" (Ainsworth et al. 1978; Bowlby 1982). Importantly, an attachment bond is denoted by an "organization" of attachment behavior in relation to one or more specific individuals, not in any single

behavior (see ► ["Individual Variations in Attachment"](#) and Sroufe and Waters 1977). Indeed, the behaviors shown in relation to the attachment figure(s) are typically in stark contrast to behaviors shown toward other persons. Attached children will, for example, typically not make do with comfort by another person when the attachment figure(s) is present.

The key facilitator of children's development of attachment is that a caregiver is being continuously available and responding to the child's attachment behaviors (not feeding, see ► ["Psychodynamic Foundations"](#)). Children can form attachments to multiple caregivers, and the caregiver's sex is unimportant (e.g., mothers are not by default more suited as attachment figures; Ainsworth et al. 1978; Bowlby 1982). Children are however thought to organize their attachment relationships in hierarchies (turning to the one highest in the hierarchy first if that person is present), and since mothers' are usually the primary caregiver (particularly early in children's lives), they are often at the top of children's attachment hierarchies.

The slow development of attachment is thought to be in part due to the immature state of the attachment system at birth (see ► ["Evolutionary Foundations of the Attachment System and Its Functions"](#)). The slow development is also due to the fact that children need repeated attachment-related experiences with their caregivers for an attachment bond to be formed. That is, organization of attachment behavior in relation to a specific person necessitates having formed representations of the other and what to expect from that person, particularly as regards availability for protection and support (i.e., as a secure base and safe haven). Indeed, drawing from cognitive psychology, Bowlby argued that experiences with caregivers lead to the development of cognitive-affective representations of self and others, which he termed "internal working models" (IWMs) and which he considered complementary in nature (Bowlby 1982; see ► ["Evolutionary Foundations of the Attachment System and Its Functions"](#)). Once formed, these IWMs, also termed "attachment representations," come to guide children's attention,

behavior, and displays of affect in relation to the caregiver, particularly in situations when the attachment system is activated.

The attachment system is also moderately environmentally labile, being open to learning and thereby permitting modifications to suit the child's environment. This openness is seen in the relation between the characteristic patterns (quality) of caregiving (e.g., sensitivity) that children receive and the different patterns of organization of attachment behaviors (i.e., quality of attachment) that children develop (see ► [“Individual Variations in Attachment”](#)). Briefly, Mary Ainsworth, who collaborated closely with Bowlby, found that children tend to show three different organized patterns of attachment, corresponding to the patterns of caregiving they have received during the first year of life (Ainsworth et al. 1978). Secure children, having received sensitive care, show a good ability to use their caregiver as a secure base and safe haven. Insecure-avoidant children, whose bids for proximity have been rejected, show an inability to turn to their caregiver when (mildly) distressed (i.e., a minimizing pattern). Insecure-ambivalent/resistant children, having received inconsistent sensitivity, show an inability to explore the environment, demanding comfort from their caregiver without being comforted by the contact (i.e., a maximizing pattern). Mary Main subsequently discovered a fourth group of children, termed insecure-disorganized/disoriented (Main and Solomon 1990). Disorganized children tend to have experienced frightening/frightened behaviors from their caregiver (Main and Hesse 1990) and show an inability to sustain an organized pattern of attachment behavior in relation to the caregiver. Variations in attachment are therefore generally described using two dimensions (secure-insecure, organized/disorganized-disoriented), subsuming four different patterns. Importantly, insecure children are attached to their caregivers. Profound difficulties forming attachments to others (i.e., reactive attachment disorder [RAD]; see ► [“Disorganized Attachment and Reactive Attachment Disorder”](#)) are typically reserved for children who have not had any caregiver consistently available (e.g., children growing up in some institutions).

Conclusion

As outlined by Bowlby, children are endowed with an attachment behavioral system and attachment behaviors and form strong bonds to caregivers that are (sufficiently) available and respond to their signals. The core function of attachment is maintaining proximity to caregivers, which have served an adaptive function of increasing chances of survival in primate species' typical ancestral environments. Offspring–parent attachment therefore denotes a hierarchical bond between children (the smaller and weaker part) and their caregiver(s) (the stronger and wiser part).

The tendency on women to seek older partners

Introduction

As a general rule, heterosexual women like their male partners to be slightly older than they themselves are (Kenrick and Keefe 1992). The average age disparity between women and their male partners (real or imagined) has been consistently estimated at 2–6 years, but the preference for older men decreases slightly as women grow older, and at about 45 years of age, women no longer show a preference for older men (Antfolk et al. 2015; Kenrick and Keefe 1992). However, a lot of important information is lost when only looking at the mean population preference. A closer look at the distribution of age disparity from population-wide marriage data shows that approximately one-third of married women in the USA have a partner that is less than 1 year older (or younger) than they themselves are. Somewhat ironically, the most common “age disparity” is thus one where there hardly is any age disparity at all. The aforementioned mean disparity in the population therefore stems from the fact that whereas approximately 18 % of women have a male partner who is more than 6 years older, less than 4 % of women have a male partner who is more than 6 years younger (US census bureau 2013). More simply put, women tend to partner up with men of their same age, but when this is not the case, women more commonly partner up with an older man than with a younger man.

This general preference for men that are equally old or older has been explained as a consequence of the human bi-maturation process, by which women mature at a younger age than men (e.g., van den Berghe 1992). Accordingly, sexually mature women would look for sexually mature men, and because men tend to mature later, there would be more interesting older men than there would be interesting younger men. Although not explicitly mentioned in this type of reasoning, this model could also

explain why the preference for older men is more apparent in young women compared to older women: Women will at some given age find equally many interesting younger men as interesting older men, all of who are mature. It is, however, important to also note that age in itself is not likely a very important feature. Age is rather a proxy of other reproductively important features (e.g., fertility and/or maturity, available resources, social status). Whereas some of these features may be strongly associated with age and lead to a strong age-related preference (e.g., female age and fertility and men's preference for young women), other features show a weaker association with age and lead to less marked age-related preferences. With this in mind, it is a noteworthy finding that women put less emphasis on a partner's age than men do (e.g., Sprecher et al. 1994). The features that women cross-culturally tend to report as important in their choice of partner are, for example, social status, financial resources, and health (Buss 1989). These are all associated with age, but the association is not very strong and its strength will vary across time and cultural contexts (Buss et al. 2004). If older men (vs. younger men) usually have a higher social status and have more resources that can be directed to a child and its mother, the theory suggests that women would then for these reasons be attracted by older men. The same features in a young man would also make him attractive, but these features are simply less common among young men. Health, on the other hand, tends to decrease with age, but because some but not all men remain healthy even as they grow older, older men displaying signs of health and vitality might be particularly interesting to women (Boothroyd et al. 2005). Sean Connery (85 years old at the time of writing), Robert Redford (79), Harrison Ford (72), Dustin Hoffman (78), and Clint Eastwood (86) definitely have something most other men of their age do not – they are maybe not healthier than the average 25 year old man, but their health and vitality are unusually apparent given their age.

Any complete evolutionary model should not only attempt to explain the average preference but

also provide an explanation for several forms of variation. Concerning age preferences there is variation across cultural contexts, variation between individuals within the same cultural context, and even variation within the same individual over time. With respect to women's mate preferences, cross-cultural variation has, for example, shown that preferences for masculinity are stronger in areas with high pathogen stress (DeBruine et al. 2010) and that cultural empowerment of women (e.g., access to education) decreases the age disparity between married men and women (Casterline et al. 1986). A lot of research focusing on variation in mate preferences within the same female has focused on the variations across the menstrual cycle, and while there is some controversy regarding the robustness of these findings, women seem to increase their preference for high status and available resources during the fertile phase of the menstrual cycle but much less is known about whether age preferences also vary (Gildersleeve et al. 2014). Fewer studies have specifically investigated the between-individual variation in women's age preferences and the biological and environmental mechanisms behind them. One factor that has received some interest is whether the absence or presence of a biological father changes partner preferences. Although the absence of a father is associated with earlier menarche (Belsky et al. 1991), indicating earlier maturation – which according to the theory of bi-maturation would predict also a preference for older men – research results regarding age preferences are limited.

Conclusion

In sum, the variation in women's age preferences can be explained by multiple contextual, personal, and biological factors. The on-average preference for equally old or older men is also likely to be the result of several processes: Women reach maturity at a younger age than men, several features that are attractive to many women are more likely to be found in older (vs. younger) men, and some signals become more apparent in older (vs. younger) men. While all these processes contribute, a lot of

potentially important contributing factors need to be investigated in order to fully explain the variation in women's age preferences. It is also important to consider that most older men are interested in younger women (Antfolk et al. 2015; Kenrick and Keefe 1992) but that only some of these men display the features necessary to attract younger women. It is thus possible that relatively few women are interested in old men per se and that the observed age disparity is the result of many old men being attracted to relatively young women. Large age disparities could consequently be the result of preferences of men with above-average mate value.

Definition

Olduvai Gorge is a world famous paleoanthropological site in Tanzania that has yielded a series of important fossil remains of early humans.

Introduction

Olduvai Gorge, located on the Serengeti Plain in northern Tanzania, has been carved over the last 200,000 years by water erosion. The sediments within the gorge range in age from late Pliocene to late Pleistocene in age. While it became known to scientists in the early twentieth century, the work by Louis Leakey began in 1931 and eventually yielded a series of fossil remains and stone tools. These discoveries have made Olduvai Gorge one of the most famous sites for human fossil remains in the world.

Importance of the Site

A variety of important human fossil specimens have been recovered from Olduvai Gorge. The first, discovered in 1959, is OH (Olduvai Hominid) 5. OH 5 is the type specimen of *Paranthropus (Australopithecus) boisei*, a robust hominid with huge jaws, very large molars, and expansive chewing muscles as evidenced by broad attachment areas for those muscles on the skull. Though this specimen dates to the appropriate time period, Leakey did not consider OH 5 to represent the toolmakers at Olduvai Gorge. This role was later filled by a series of discoveries that Leakey and his colleagues Phillip Tobias and John Napier placed into the species *Homo habilis*. These fossils, which included the type specimen OH 7, plus OH 8, OH 13, and OH 24, have more lightly built faces with smaller teeth. OH 7 also included several hand bones, which were interpreted as enabling both a power grip and a precision grip necessary to manufacture stone tools. The species *Homo erectus* has also been found at Olduvai Gorge and is most famously represented by the specimen OH 9.

The “Zinj” site (FLK Zinj) at Olduvai Gorge, which produced the OH 5 specimen, also held a huge cache of animal bones. Many of these bones show signs of having been cut by stone tools, leading some to interpret the site as evidence of hunting by early humans. Some interpretations of the “Zinj” site suggested that it may have represented a home base for early humans, who were bringing meat back to provision a family or group who were camping at this site (see Bunn and Kroll 1986; Rose and Marshall 1996). Other work on these fossils is more strongly supportive of humans primarily scavenging carcasses at Olduvai (e.g., Blumenschine et al. 2012; Pante et al. 2012), but these interpretations remain somewhat controversial.

The oldest stone tool complex, known as the Oldowan, was defined based on artifacts discovered at Olduvai Gorge. The Oldowan is characterized by very simply made stone tools, manufactured by “hard hammer” (stone on stone) flaking. Choppers are the most common artifact type and are basically a stone that has

had flakes chipped from it to create a crudely sharpened edge. Flakes were also sometimes utilized by early hominids, but most commonly, the choppers were the primary focus. Oldowan tools are highly variable in their manufacture and lack the planning and skill evident in later stone tool technologies.

Conclusion

Olduvai Gorge is one of the most famous, and important, fossil sites in the world, and its importance to the study of human evolution cannot be overstated. It has provided key fossil evidence and crucial insights into aspects of early human behavior.

Definition

A structure located in the forebrain of vertebrates that receives neural input about odors detected by cells in the nasal cavity.

Introduction

The environment, if filled with odorant molecules, and our emotions, moods, and behaviors may be controlled by olfactory stimuli. The first steps in processing olfactory signals are transducing and relaying odorant information centrally from olfactory receptor neurons (Purves et al. 2001). Receptor axons combine to form a large number of bundles making up the olfactory nerve. The target of the olfactory nerve on each side is the olfactory bulb. The olfactory bulb is an evaginated cortical structure that lies on the ventral anterior aspect of the ipsilateral forebrain and contains two main types of projection neurons and interneurons that receive primary afferent input from sensory neurons (Greer et al. 2008).

The Architecture of the Olfactory Bulb

The main olfactory bulb has a multilayered cellular architecture consisting of the glomerular layer, the external plexiform layer, the mitral cell layer, the internal plexiform layer, and the granule cell layer. In young adult humans, the olfactory bulb is connected by long olfactory stalk or peduncle and

is pulled forward from its point of attachment to the cerebral hemisphere (van Hartevelt and Kringelbach 2012). In most young adult humans, it is about 50–60 mm³ on each side (Turetsky et al. 2000). The olfactory nerve fibers make up the olfactory nerve layer and pass through the cribriform plate from the nasal cavity (van Hartevelt and Kringelbach 2012). This nerve layer appears to be thick where the nerves reach the olfactory bulb. The olfactory nerve fibers terminate in the glomerular formation.

Laminar Structure of the Olfactory Bulb

Every layer in the olfactory bulb is comprised of different types of neurons. The neurons in the olfactory bulb have been categorized according to the layers in which their cell bodies are found. According to this categorization, the juxtglomerular cells are found in the glomerular layer, tufted cells in the external plexiform layer, mitral cells in the mitral cell layer, and granule cells in the granule cell layer (Nagayama et al. 2014).

In the glomerular layer, neurons are morphologically heterogeneous and can be categorized in three types: Periglomerular cells (PG), superficial Short-Axon cells (sSA) and External Tufted cells (ET) (Pinching and Powell 1971). Most of these cells solely function within the olfactory bulb and do not innervate other brain regions. The most abundant type of neuron in this layer is the PG cell, which is the smallest in diameter, and most of the time they project their dendrites to a single glomerulus. These cells are thought to have an axon which terminates in the interglomerular space (Nagayama et al. 2014). Pinching and Powell (1971) were the first to report the sSA cell. These cells are found in the glomerular layer in a small percentage and are slightly larger than PG cells. They have dendrites that course exclusively in the interglomerular space, with an axon that extends as far as 1–2 glomeruli (Pinching and Powell 1971). The ET is the largest of the three types and has primary dendrites which are generally mono-glomerular. These

cells occupy a large volume of the glomerulus (Nagayama et al. 2014).

Mitral and tufted cells extend their dendrites within the glomerulus of the external plexiform layer (EPL), where they process odor signals. The odor signal reaches the cell body of tufted cells in the EPL and mitral cells in the mitral cell layer (MCL). The process by which back-propagation is conducted throughout the dendrites until it is blocked by local inhibition from granule cells is called lateral inhibition (Xiong and Chen 2002). The lateral inhibition mechanism by which activation of mitral and tufted cells occurs is associated with one glomerular molecule which is associated with neighboring glomerular molecules (Buonviso and Chaput 1990). This layer includes mostly dendritic fibers that are secondary dendrites. These dendrites are made up of mitral-tufted cells and apical dendrites of granule cells which are morphologically similar in that they both extend a single primary dendrite to one glomeruli from the thousands that are found in the olfactory bulb (Nagayama et al. 2014). This process signifies that each projection neuron receives odor information originating from only a single receptor. However, the lateral inhibition processes, which occurs through the dendrodendritic reciprocal synapses with granule cells, may enhance the contrast between strongly activated and faintly activated glomeruli. Thus, it may tune further the specificity of individual mitral and tufted cells to odor molecules. Therefore, it is possible that second-order mitral and tufted cells may be more tuned to specific features of certain molecules than sensory neurons (Yokoi et al. 1995).

The granule cell layer (GCL), of the olfactory bulb, is mostly occupied by granule cells. These cells are inhibitory interneurons with a small cell body, and they are divided into subgroups based on their morphological differences. Some granule cells can be found in other layers of the olfactory bulb, but they are generally found in the GCL. In order for the apical dendrite that they have to extend towards the surface of the olfactory bulb, it first has to ramify the EPL where granule cells have spines used to form synapses with the

secondary dendrites of mitral and or tufted cells (Nagayama et al. 2014). Because granule cells lack an axon, their output relies solely on dendrodendritic synapses. In addition to the granule cells, the GCL comprises of other interneurons called the short-axon cells (sSA). These short-axon cells have larger cell bodies than granule cells, and their dendrites rarely extend beyond the MCL. However, they have axons that extend to different layers of the olfactory bulb (Merrick et al. 2014).

The olfactory bulb is a complex system made up of various layers which interconnect in order to discriminate between thousands of odors (Bushdid et al. 2014). This is mostly due to the variety of odorant receptors that bid to different odorants with specific affinity profiles. The olfactory bulb is made up of multiple types of neurons that form a complex network in order to process information before it is transmitted to the olfactory cortex.

The Function of the Olfactory Bulb

The function of the olfactory bulb is mainly to recognize and discriminate a large number of different odors. In order to accomplish this, a series of information processing steps, at distinct anatomical sites of the olfactory system, take place. The initial recognition occurs in the olfactory receptor neurons which are located in the nasal epithelium (Ngai et al. 1993; Buck and Axel 1991). In the second step, the olfactory receptor neurons project axons to glomeruli in the main olfactory bulb, where synaptic connections with mitral and tufted cells take place (Kauer and Cinelli 1993). In the next layer, the external plexiform layer, mitral, and tufted cells form dendrodendritic synaptic contacts with the granule cells. These synapses undergo reciprocal regulation (Trombley and Shepherd 1993). Each granule cell shows divergent dendrodendritic synaptic contacts with a vast number of neighboring tufted and mitral cells, suggesting the induction of lateral inhibition of neighboring mitral and tufted cells (Rall et al. 1966; Scott et al. 1993). In the

following paragraphs, the function of each layer is further discussed.

The most distinctive characteristic of the olfactory bulb is probably an array of spherical accumulation of neuropil, signal processing molecules called glomeruli (Mori et al. 1999). Within glomeruli lie axons of olfactory sensory neurons from excitatory synaptic connections on dendrites of mitral and tufted cell which are the output neurons of the main olfactory system (Buck 1996). The odor molecule information enters the olfactory systems through the mitral and tufted cells and is then processed by the local neuronal circuits that mediate synaptic interactions within the molecule of the main olfactory system (Mori et al. 1999). The mammalian olfactory system can detect and discriminate a large variety of odor molecules. In order to distinguish between diverse odor molecules, mammals have developed approximately 1000 receptors (Axel 1995; Buck 1996; Yoshishara et al. 1997). These receptors are expressed on the ciliary membrane surface of sensory neurons in the olfactory epithelium. According to Maresh et al. (2008), the ratio from olfactory receptor neurons to glomeruli is 16:1 resulting in approximately 5500 glomeruli. Therefore, the initial distinction between different odors is based on specific glomeruli unit structures for olfactory discriminations (Mori et al. 1999).

Interneurons also called periglomerular cells send dendrites and axons close to glomeruli and receive synapses from the olfactory nerves. The periglomerular cell dendrites form reciprocal synapses with mitral and tufted dendrites (van Hartevelt and Kringelbach 2012). The external plexiform layer is located deep to the glomeruli and consists of dendrites of granule, mitral, and tufted cells along with the tufted cell somata which are also found scattered through this layer. At the border between of the external plexiform layer and the deeper granule layer, the mitral cell somata are located, which extend to the glomeruli (van Hartevelt and Kringelbach 2012). Approximately half of the volume of the bulb is made up of granule cells which are found

in much greater numbers than all other cells in the olfactory bulb (Bhatnagar et al. 1987). These interneurons do not possess an axon, and they form synapses with tufted and mitral cell dendrites. Studies regarding the morphometry of the olfactory bulb revealed approximately 5500 glomeruli and 40,000 mitral cells in young adults (Maresh et al. 2008; Meisami et al. 1998). These numbers were found to decline with age by about 10% each decade while the thickness of the glomerular layer was also found to be significantly reduced (Bhatnagar et al. 1987; Meisami et al. 1998; Maresh et al. 2008). This may account for the decline in the olfactory function with age (Murphy et al. 2000).

Studies on mice have shown that the olfactory epithelium contains more than two million sensory neurons which express only a single type of odorant receptor gene (Ressler et al. 1994). Although this suggests that individual sensory neurons may respond to specific odor ligands that bind to the expressed receptor, there is no indication as to which range of odor molecules individual sensory neurons tuned to (Bozza and Kauer 1998). The olfactory axon projection is based on two main principles: “zone-to-zone projection” and “glomerular convergence” (Mori et al. 1999).

Based on the expression patterns in the olfactory epithelium, the odorant receptors can be classified into four main spatial zones which are restricted in the olfactory epithelium (Sullivan et al. 1995). Within every zone neurons expressing different receptors intermingle. This type of zonal organization is also evident in the main olfactory bulb. Even though the molecular markers that distinguish glomeruli among zones are yet to be explored, studies of the main olfactory bulb suggest that their might be four spatially segregated zones similar to the zones in the olfactory epithelium (Vassar et al. 1994). Ressler et al. (1994) found that information highly distributed in the nose is transformed in the olfactory bulb of the brain into a highly organized spatial map. The spatial and numerical characteristics observed in their study indicate that in the olfactory bulb,

olfactory information is remarkably organized into a stereotyped map that makes discrimination between different odors possible. Therefore, odor information received by sensory neurons in a given zone of the olfactory epithelium is thought to be transmitted to glomeruli and then transferred to mitral and tufted cells in the corresponding zone of the main olfactory bulb (Ressler et al. 1994).

Glomerular convergence, the second type of olfactory projection, refers to the ability of the olfactory axons to bind their specific target glomeruli in the olfactory bulb. A glomerulus receives axonal inputs from thousands of olfactory receptor neurons that all express the same olfactory receptor (Al Yamani et al. 2012). In other words, as recent studies have shown, olfactory sensory neurons expressing a specific odor receptor converge their axons to defined glomeruli (Imamura et al. 1986; Katoh et al. 1993; Mori et al. 1999). The implications of glomerular convergence, in terms of coding, are believed to improve sensitivity so as to ensure detection and lead to a more compact odorant representation that available at the sensory level (Laurent 1999; Al Yamani et al. 2012).

Conclusion

Research has led to discovering a large multigene family of odorant receptors which in turn triggered rapid advances concerning the architecture and function of the mammalian olfactory bulb (Buck 1996). The olfactory bulb seems to be a complex structure made up of multiple neuronal layers which contribute individually to the olfactory process. One of the first areas that was researched was the functional roles of individual sensory neurons that can be found in the olfactory epithelium. This process triggered the elucidation of the axonal projection patterns of sensory neurons to the main olfactory bulb which in turn led to the glomerular convergence, in other words the pattern of olfactory axon connectivity to the main olfactory bulb. What has

been determined by research thus far is the vast amount of odorant receptors that the mammalian olfactory bulb consists of in order to be able to translate every odor. More recent studies have shown that individual glomerular modules function as a molecular feature and that local neuronal circuits mediate lateral inhibition and synchronized spike discharges among mitral and tufted cells that belong to different glomerular molecules (Mori et al. 1999).

Definition

Unquestionably the most important book that was published in the nineteenth century and undoubtedly the most important duodecimo volume ever to be printed, Charles Darwin's *On the Origin of Species by Means of Natural Selection* is also a very good candidate for the most significant and influential book ever to be written (thus far) by a human being. The other two main candidates – Nicholas Copernicus's *De revolutionibus orbium coelestium* of 1543 and Isaac Newton's *Philosophiæ Naturalis Principia Mathematica* of 1687 – were of near-equal scientific value at the time of their first publication but were less immediately influential among the wider public than Darwin's *Origin*. A good indication of this is that in January 1860, there was an anecdotal report of a passenger enquiring about purchasing a copy of the *Origin* at a UK railway station bookseller, rather than a more usual potboiler novel.

The first edition of 1250 copies of the *Origin* published on 24 November 1859 was priced at 15 shillings and immediately sold its entire print run to booksellers, and a second edition of 3000 copies was then quickly printed on 7 January 1860. Across Darwin's lifetime, a total of six separate editions were eventually produced, the last printing of the sixth edition being in 1876 (18th thousand) and with a minor title change to *The Origin of Species* for the first printing of the

sixth edition (11th thousand) in 1872. The various editions contained significant modifications and elaborations on the original text.

For example, although it quickly became synonymous with the term “natural selection,” the phrase “survival of the fittest” was included for the first time only in the fifth edition (10th thousand) of 1869 (Browne 2003, p. 315), and a historical sketch of various precursors to the theory of evolution was first included in the third edition (7th thousand) of 1861. After nearly a decade, Darwin commented in 1868 that he had become “sick and tired of correcting” what he called the “everlasting *Origin*” (Freeman 1978, p. 221), the term “everlasting” here having multiple meanings. A centennial variorum text was eventually issued (Peckam 1959), while Darwin's two pre-*Origin* essays sketching the initial outlines of his theory of evolution from 1842 and 1844 were published together in book form in 1909 (Darwin 1909).

Introduction

Darwin had been busy working on a much larger work on “the transmutation of species” since 1837, after returning from his momentous 5-year H.M.S. *Beagle* voyage in 1836, this larger work from 1854 being provisionally titled *Natural Selection*. However, on 18 June 1858, he received a package from his fellow naturalist Alfred Russel Wallace that forced his hand into publishing a shorter “abstract” of the theory of evolution in book form: this became *On the Origin of Species by Means of Natural Selection* of 1859. Wallace had independently discovered many of the most important components of Darwin's theory of species origin, so it was decided that both naturalists should communicate short papers to a Linnean Society meeting (which were read on 1 July 1858) informing the public of the outlines of their theory, thereby sharing the credit for the new discovery equally between them (Darwin 1977 [1858]; Wallace 1977 [1858]).

Even so, it was Darwin's *Origin* that instantly became the definitive guide to the new scientific theory of evolution, with Wallace's various works

quickly taking second place in terms of both their scientific importance and their wider public impact (Cohen 1985, p. 603). Although the initial preeminence of Darwin's book over Wallace's works in the 1860s was in large part facilitated by Darwin's superior mustering of a wide variety of natural history data and his superior presentation of the theoretical arguments, it was also in part facilitated by the form and structure of *On the Origin of Species* as a book, and by the fact that in it, Darwin was first to controversially imply that "the origin of man and his history" could be explained by the same principles as the evolution of all other species and behaviors (Darwin 1872 [1859], p. 428).

Wallace had been much more hesitant on this issue than Darwin, positing that what Wallace called some "unknown cause or power," which had yet to be identified by naturalists, was required to explain the higher intellectual and moral aspects of human behavior, implying that they were too complex to explain by natural selection (Wallace 1889, pp. 463–464). Darwin's bulldog-advocate T.H. Huxley was quick off the block in expanding on precisely what "the origin of man" actually meant in its Darwinian meaning in his *Evidence of Man's Place in Nature*, with its opening chapter focusing directly on "the Man-Like Apes" and its subsequent search for "a Man more pithecoïd" than any yet known (Huxley 1863, p. 184). It was confirmed in 1904 that the closest primates to human beings were the apes (Nuttall 1904).

Although *On the Origin of Species* had been composed at a speedy rate over 14 months across 1858 and 1859, Darwin had based it in substantial part upon his previous two decades of study and composition for the proposed *Natural Selection* volume, so the *Origin* was a compact distillation of a very substantial research program. As has been explained: "Composed in bursts of furious activity separated by debilitating bouts of illness, it was a compromise between the compact, accessible essay he had written in 1844 and the all-inclusive, massively documented 'big book' that he hoped to write" (Van Riper 2008, p. 49). Much of Darwin's larger *Natural Selection* is now available for scholars to consult, so the exact relation

between it and the *Origin* can be traced in many instances: out of the 14 main chapters of the *Origin*, "nine had been preceded by extensive treatment in *Natural Selection*" (Stauffer 1975 [1856–58], p. 10). Unusually for such an important book, the *Origin* contained no formal references, but the real sources are often traceable by consulting *Natural Selection*.

Evolutionary Mechanisms in the *Origin*

Although the title of Darwin's book suggested that evolution occurred only "by means of natural selection," in fact, Darwin's theory of descent with modification posited that various different mechanisms of evolutionary change existed, these conventionally being cited as natural selection, sexual selection, and artificial selection. His theory of evolution is, therefore, perhaps most accurately described as the theory of evolution by selection mechanisms, instead of the more commonly encountered theory of evolution by natural selection.

All three of the outlined mechanisms were explicitly considered to varying degrees in *On the Origin of Species*, although only one chapter of the book (Chap. IV on "Natural Selection") was explicitly named after one of them. Within Chap. IV, Darwin also presented something called "the principle of divergence" as being of fundamental significance to his theory of evolution. Whether divergence can be conceived of as a separate fourth type of evolutionary mechanism – christened here as divergent selection – will be considered in what follows (Barnett 2019).

Natural selection is the process by which the slight variations that occur through descent with modification in species are either preserved or not preserved, depending on whether they are advantageous to the animal and thereby aid further reproduction. Or, as Darwin posited in the *Origin*: reproduction, inheritance, variability, the struggle for life, processes which then produces selection (Darwin 1872 [1859], p. 429). Sexual selection is the process by which (most commonly) females choose their mates based on some generally favored traits, features, or behaviors, thereby

selecting these traits for further enhancement, and males fight each other for this reproductive access, in what Darwin christened in the *Origin* as “the law of battle” (Darwin 1872 [1859], p. 69). Artificial selection is the process in which human beings consciously favor and develop particular species features and traits through selective breeding practices.

In the same spirit as these three forms of evolutionary selection but (arguably) conceptually distinct from them, divergent selection can be seen as the process by which local environments, or what Darwin termed “the same spot” in the economy of nature, will act to favor the evolution of what he called “very diverse forms” of animal and plant life (Darwin 1872 [1859], pp. 9–10). This evolutionary divergence takes place both in terms of the diversification of behavior and habit and also in terms of diversification of structure and constitution (Darwin 1872 [1859], p. 89). How divergent selection operates is that “the varying offspring of each species will try . . . to seize on as many and as diverse places in the economy of nature as possible” (Darwin 1872 [1859], p. 10).

This in turn means that the more varying in terms of utilizing resources in a specific local environment a given species can be, i.e., the more that they can use resources that the other existing species that occupy the same environment and ecosystem do not use or use to a lesser degree, the more likely they will be to prosper and propagate. Divergent selection thus provides one type of “directionality” to evolutionary change within specific local environments and ecosystems. Divergent selection can be conceived of as operating in a similar manner to sexual selection, but instead of female choice and male-male conflict being directing forces, the local environment and the local wildlife are (together) the directing forces. They act to channel evolutionary change into a more optimal use of local resources by “diverging” the existing forms of life so as to facilitate them in occupying different behavioral, structural, and resource using niches from those niches – or local ecosystems (Eldredge 1989, p. 129) – that have already been occupied by existing species.

That Darwin recognized a distinction between natural selection and divergent selection is evident from his statement that the “complex action of these several principles, namely, natural selection, divergence & extinction, may be best . . . illustrated by the following Diagram” (Darwin in Stauffer 1975 [1856–58], p. 238), this being the “tree of life” diagram illustrating the evolution of species from the *Origin* (Darwin 1872 [1859], pp. 90–91). At another point he specified “natural selection, extinction & divergence” as three distinct evolutionary processes that had been going on “since the dawn of Life” (Darwin in Stauffer 1975 [1856–58], p. 246). Hence, arguably, divergent selection is articulated as a separate fourth evolutionary mechanism within the *Origin*.

Speciation in the *Origin*

Although he did employ any strict definitional terminology in the *Origin*, it is evident that Darwin recognized that species could evolve in a number of different ways. For example, they could evolve in a very gradual linear manner while remaining in the same location (straight-line evolution); they could evolve more quickly upon reaching a new geographical area; they could evolve in response to large-scale geological and/or environmental changes; or they could evolve in response to the encroachment of their habitat by new species (Darwin 1872 [1859], pp. 282–289). Darwin provided a concise distillation of his approach to the different factors that contributed to the process of speciation in the *Origin* as follows:

The process of modification must be slow, and will generally affect only a few species at the same time . . . Whether such variations or individual differences as may arise will be accumulated through natural selection in a greater or less degree . . . will depend on many complex contingencies – on the variations being of a beneficial nature, on the freedom of intercrossing, on the slowly changing physical conditions of the country, on the immigration of new colonists, and on the nature of the other inhabitants with which the varying species come into competition. (Darwin 1872 [1859], p. 291)

Hence for Darwin, one species might remain unchanged over a very long period of time, while another might change very gradually, yet another at a much faster pace, depending on how the various factors identified above interacted, or how the “complex contingencies” played out in any given instance.

It is also evident from the *Origin* that Darwin, at least implicitly, distinguished between straight-line or phyletic evolution, in which a single species as a whole becomes modified over time in response to environmental or competitive pressures, and what is now called cladogenesis, where one parent species splits into two or more different resultant species in response to these pressures (Archibald 1997, p. 693; Darwin 1872 [1859], p. 293). The well-known hypothetical phylogeny figure (or fold-out illustration) in the *Origin*, inserted between pages 90 and 91 (of the sixth edition), illustrated the fates of 11 species, 9 of which undergo straight-line evolution and the remaining two experience cladogenesis.

Extinction in the *Origin*

Although Darwin is most commonly portrayed in the literature as an extinction gradualist, in fact both the gradualist and punctuated equilibrium approaches can be found outlined within the *Origin*. He accepted that, most commonly, background extinction of individual species occurred via natural selection, i.e., the gradual extinction of species occurred through interspecies competition (Sepkoski 2008, p. 225), species extinction usually being for Darwin “a slower process than their production” (Darwin 1872 [1859], p. 294). However, it is now known that near-instantaneous mass extinction events, defined as when more than 50% of all species disappear (Van Couvering 2000, p. 262), have sometimes occurred; as Darwin duly recognized in the *Origin*, “the process of extinction may have been rapid” in some cases of large-scale natural calamities such as the subsidence of an island or the eruption of a volcano (Darwin 1872 [1859], p. 294).

A key role allotted to extinction in the *Origin* was that it “played an important part in defining

and widening the intervals between the several groups in each class” of species (Darwin 1872 [1859], p. 380). As many ancient forms of life had now been lost, this has served to “thin out” the remaining set of species and accounted to a degree for the lack of closely intermediate forms between some of them, or, as Darwin phrased it, extinction has defined the animal groups. Finally, for Darwin, groups of species, or genera and families, followed the same general rules in their appearance and disappearance as individual species did (Darwin 1872 [1859], p. 292).

Classification in the *Origin*

Another key aspect of the *Origin* was Darwin’s use of the theory of evolution that was articulated within it to provide a foundation for a system of classification of the whole animal kingdom into sets as phylogeny, in a chapter (XIV) entitled “Mutual Affinities of Organic Beings.” In this chapter Darwin explained regarding the importance of descent with modification that:

... this element of descent is the hidden bond of connection which naturalists have sought under the term of the Natural System. On this idea of the natural system being . . . genealogical in its arrangement, with the grades of difference expressed by the terms genera, families, orders, &c., we can understand the rules which we are compelled to follow in our classification. We can understand why we value certain resemblances for more than others . . . and how the several members of each class are connected together by the most complex and radiating lines of affinities. (Darwin 1872 [1859], p. 381)

This system of classification can, for Darwin, also be used to assist in the understanding of animal morphology, defined by Darwin as the law of form independent of function, as “members of the same class . . . resemble each other in the general plan of their organisation,” or their overall body structure (Darwin 1872 [1859], p. 382).

Although the system of animal and plant classification in its basic outline nomenclature had been initially provided by Carolus Linnaeus in the eighteenth century, what Darwin added through the *Origin* was the correct framework

for understanding the links between the different members of the total animal set and of how the various members had been temporally connected. He consequently proposed a historical taxonomic methodology for classification that was based on an understanding of species evolution as a branching process (Richards 2008, pp. 164–165).

In relation to animal morphology and classification as revealed in the fossil record at it was understood at the time of the *Origin*, Darwin's resolute belief in the theory of evolution by selection mechanisms is demonstrated by his attitude to what was (arguably) the most significant obstacle to this theory when it was first proposed. This obstacle was that, according to the scientific understanding of the period, the earth was simply not old enough to have provided the length of time to facilitate the evolution of all the life that had been observed on it (and discovered in it within the fossil record), an obstacle that Darwin readily admitted to in the sixth edition of the book.

His response was that it was possible that the very early period of the earth's history had been subjected to more violent and rapid changes than those currently occurring, which would have increased the pace of evolution in this period (Darwin 1872 [1859], p. 286). This was not a particularly convincing proposition, but this defense was enough for Darwin to remain fully convinced of the accuracy of his theory. He should instead have argued that the theory of evolution by selection mechanisms itself provided sufficient evidence that the earth was older than the scientific theory of the time allowed.

Geographical Distribution in the *Origin*

According to Darwin, the theory of descent with modification in the *Origin* also assisted with an understanding of the leading facts in the observed patterns of species distribution across the globe. He explained on this issue that:

We can see why there should be so striking a parallelism in the distribution of organic beings throughout space, and in their geological succession throughout time; for in both cases the beings have been connected by the bond of ordinary generation,

and the means of modification have been the same ... On this view of migration, with subsequent modification, we see why oceanic islands are inhabited by only a few species, but of these, why many are peculiar or endemic forms. (Darwin 1872 [1859], p. 418)

In the chapter on “Geographical Distribution” (XII) in his book, Darwin listed what he called “three great facts” regarding distribution across the globe, the first being that neither the similarity nor the dissimilarity of the inhabitants of various regions could be wholly explained by climatic and other physical conditions. The second was that barriers or obstacles to free migration were clearly related to the observed differences between the productions of various regions. The third was that the observed affinity of the productions of the same continent or the same sea, even though the species themselves were distinct, was very noticeable (Darwin 1872 [1859], pp. 316–318).

According to Darwin, all of these three facts served to corroborate the theory of evolution by selection mechanisms or the veracity of descent with modification. Darwin also affirmed the idea that each species was initially produced in one area alone, with subsequent migrations then producing some degree of both straight-line evolution and cladogenesis (Darwin 1872 [1859], p. 321). Documenting the geographical distribution of animals across the planet was one of the few areas where Wallace's contribution to natural history eventually exceeded that of Darwin (Wallace 1876).

Instinct in the *Origin*

The chapter (VIII) on instinct is by far the most neglected chapter of the *Origin* among contemporary biologists, but many evolutionary psychologists trace the origin of their subject to this key section of Darwin's book. However, in the sixth edition of the *Origin*, Darwin gave precedence on the application of the evolutionary method within psychology to Herbert Spenser and his book *The Principles of Psychology* (Darwin 1872 [1859], p. 428), the first edition of which had been published 3 years prior to the first edition of the

Origin, Spenser's book containing a chapter-length account of instinct (Spencer 1855, pp. 539–553).

Darwin declared at the start of chap. VIII of the *Origin* that “instincts are as important as corporeal structures for the welfare of each species” (Darwin 1872 [1859], p. 206), and he then outlined his theory that most instincts had evolved by selection mechanisms acting on random variations in just the same way as organic corporeal structures had. As he explained: “why should not the brain, as well as all other parts of the body, sometimes vary in a slight degree,” with favorable mental variations then being preserved (Darwin 1873, p. 417). Darwin also allowed that some instincts could evolve or become modified by slow degrees through inherited habits (Darwin 1872 [1859], p. 206), which is not necessarily Lamarckian if the Baldwin effect – in which natural selection “lays down” the learnt habit as a form of instinct – is allowed (Weber and Deprew 2007).

Although Darwin did not explicitly define the concept of instinct in the *Origin*, elsewhere he defined an instinctive act as the “performance of any action without the aid of experience, or instruction or sufficient reasoning powers” (Stauffer (1975 [1856–58]), p. 468). He believed that a large number of instincts existed in both animals and human beings, and in addition to in the *Origin*, he also discussed them in detail in *The Descent of Man*. He categorized instincts into two basic types, individual and social instincts. Individual instincts such as imitation were seen by Darwin as more basic than social instincts such as community defense, but social instincts like the maternal instinct could override individual instincts like self-preservation (Darwin 1874 [1871], pp. 107–108). He also distinguished between simple and more complex instincts and between constantly operating instincts and those that only function at certain points in an animal's life.

Another key element of Darwin's theory of instincts was that different instincts had different strengths and persistence/endurance levels, as had been evolved by selection mechanisms, meaning

that when some instincts came into conflict with others, the stronger and more persistent instincts would usually win out. For example, he cited the migratory instinct in birds as conquering their maternal instinct in certain instances and the social instincts as a group being generally stronger than the less persistent instincts. He also asserted that individual animals of the same species possessed many of the same instincts but at varying strengths and persistence levels (Darwin 1874 [1871], pp. 99–110).

Darwin's work on instinct and animal intelligence was continued by George Romanes, who published Darwin's “Posthumous Essay on Instinct,” removed from the *Origin* “Instinct” chapter to save space (Romanes 1895, pp. 355–384). The first professional psychologist to take up Darwin's approach to instinct was William James, who first coined the now-familiar term “evolutionary psychology” in *The Principles of Psychology* with a memorable chapter subheading: “Evolutionary Psychology Demands a Mind-Dust,” or a mind-stuff theory of compound mental states (James 1891, 1: 146). James also discussed psychogenesis or the origin of instincts as an entirely natural process along Darwinian lines (James 1891, 2: 688). Although contemporary evolutionary psychologists have discarded James's mind-dust, they still employ – albeit in a much more sophisticated form – a modernized version of Darwin and James's formulation of the instinct concept as evolved psychological mechanisms.

The Initial Reception of the *Origin*

The initial reception of Darwin's book is best described as mixed. Some naturalists were very enthusiastic; Wallace, for example, characterized the *Origin* as immediately elevating Darwin to the exalted status of “the Newton of natural history” (Wallace 1889, p. 9), and Huxley was also very positive, writing a number of reviews defending Darwin's work as an important scientific advance. Others looked upon the book much less favorably. The astronomer John Herschel, for example,

gently mocked the theory of evolution by selection mechanisms as “the law of higgledy-piggledy” and implied that nature’s regularities could not conceivably be simply random variations (Hull 2002, p. E11). The geologist Adam Sedgwick wrote that to accept Darwin’s case for evolution would “sink the human race into a lower grade of degradation” than ever before (Browne 2003, p. 94). Darwin himself referred in 1860 to experiencing a “storm of hostile reviews” of the *Origin*, with one such reviewer asking if it was credible that “turnips are tending to become men” (Dorsey 1928, pp. 184–185).

However, some reviews raised more perceptive unresolved problems. For example, one reviewer pointed out that to finally demonstrate the reality of natural selection, a quantitative and precisely measurable account of key elements of it such as variation, advantage, rate of survival, and rate of reproduction would be required, something that Darwin had not really supplied (Gayon 2003, p. 250). As Huxley astutely judged, what Darwin had provided in the *Origin* was a brilliantly argued and very convincing interrelated set of hypotheses (Huxley 1863, pp. 125–128), but these required further empirical support before they could all be taken as proven fact.

It is also accurate to state that some parts of the theory were initially treated far more favorably than others. Many naturalists subsequently accepted that species could evolve in some general way; some accepted natural selection as a mechanism partly responsible for this evolution, but sexual selection as a mechanism was treated with far greater skepticism across the remainder of the nineteenth century. Even Wallace questioned the need for (and effect of) sexual selection, arguing (erroneously) that female preference in choosing ornamental traits would be neutralized by other selection mechanisms, as “the extremely rigid action of natural selection must render any attempt to select mere ornament utterly nugatory” (Wallace 1889, p. 295). And Darwin’s principle of divergence, here conceived of as divergent selection, was quickly subsumed within natural selection and lost its key separate place in his theory.

Conclusion

As others have already noted, the title of Darwin’s book – *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life* – is actually misleading in various different ways. The book does not consider “the origin of species” at all, but rather only how species evolve; species evolve not “by means of natural selection” but by means of natural, sexual, artificial, and (arguably) divergent selection; “favored races” are not preserved in the struggle for life, but varieties and species well-adapted to their environments are. In the few instances where Darwin used the term “race” in the text of the book, he immediately clarified that what he really meant was “variety” (Darwin 1872 [1859], p. 12).

Despite being misleading in these literal senses, Darwin’s *Origin* title still works very effectively on both the metaphorical and conceptual levels at connoting the book’s central importance to the fields of natural history, evolutionary biology, and evolutionary psychology, and the book’s content – framed effectively by its author as “one long argument” designed to untangle the ever-branching bank of nature – has provided an inspirational foundation from which endless variant forms of understanding of the natural world have been and are being evolved.

Definition

A Web-based survey used to collect information.

Introduction

As mentioned in the Surveys and Questionnaires section, data collection can occur online. Online methods can present unique benefits when compared with traditional survey methods, but they also come with a unique set of challenges. This section will discuss some of the advantages and disadvantages to using online methods, some ways to improve the quality of data collected online, and, finally, one commonly used source of online participants, Amazon Mechanical Turk.

Benefits of Online Surveys

Many of the positive aspects of online surveys revolve around the ease of creation and use, broad reach, low associated expense, and quick turnaround when compared to traditional survey methods. Online methods can be developed easily and quickly through software specifically designed for survey creation or through word-processing software. Often when using survey-specific software, a researcher can use methods that would not be possible with traditional methods, such as embedding multimedia (e.g., videos, pictures) or measuring reaction times. Additionally, these types of software often can automatize the process, allowing researchers to reuse previous questions without manually typing them, randomizing questions and answers, sending reminders to participants to complete the survey, and providing data in a format that is ready to analyze.

Another benefit to utilizing online surveys is the broad reach offered by the Internet. Researchers are easily able to contact people across the world with various demographic backgrounds. The Internet can also serve researchers looking to study relatively small populations through sites that specifically cater to those smaller populations. Sampling for surveys can

become easier through sites that provide samples, sometimes for a fee and sometimes just for the amount you wish to compensate your participants. Additionally, social media allows ease of contact for those looking to utilize snowball methods. Finally, there is less work involved for the participant, lowering the barriers to participation, as they can complete the survey on their own schedule, they do not have to travel to the research site, as with face-to-face methods, and they do not have to mail surveys back to the researcher, as with mailed surveys. These all serve to lower the costs associated with gathering a sample and compensating participants for their time.

Finally, the ease with which online surveys can be created and distributed combined with the readily available population lowers the turnaround time for online surveys. There is no longer a need to schedule times to speak with a participant, face-to-face or by telephone, or to stuff envelopes and wait for mailed responses.

Disadvantages of Online Surveys

Despite all of the potential advantages to using online surveys, there are also some potential disadvantages that need to be considered when choosing a method of survey distribution. One possible drawback is the typical user of the Internet. Often, those online are younger and more technologically savvy. This can eliminate, or greatly reduce, participation from those who are older or who do not have regular access to technology or Internet service. The self-selection of those willing to take online surveys presents a different population than those who may take telephone or written surveys. However, with the inundation of technology and the Internet into daily lives, this is becoming less and less of an issue, as even those without Internet service often have access through smartphones, and older populations are increasing online. The proliferation of technology and Internet action also presents an ethical challenge for researchers, as participants under the legal age to consent could

be participating without the knowledge of the researcher.

Another disadvantage to online methods is simply the changes in the cultural norms of the online environment. Participants are faced with a surplus of ads and information online, so capturing a participant's attention can be more difficult. A researcher has relatively little control of the environment in which a participant takes a survey; there is no way to ensure that a participant completed the survey in a distraction-free environment. Fortunately, this can be somewhat mitigated by including attention checks within the survey. Additionally, researchers face issues of attrition with online environments, especially with longer surveys. The Internet provides many distractions and with it the chance that a participant will simply not finish an entire survey, especially if they feel it is not worth their time.

Finally, technology itself can present a disadvantage. The online market is ripe with scams and phishing (i.e., malicious attempts to obtain private information), and thus the online participant may not trust the researcher with certain information. E-mail and spam filters often prevent mass e-mailing of participants, requiring researchers to find alternative methods of contacting potential participants. However, as stated above, there are services which can provide contact with willing participants.

One way to mitigate the disadvantages of online survey use, while still receiving the advantages, is to provide participants with the option to choose if they wish to complete the survey online or through alternative methods. While this may present more work for the researcher, it can result in improved response rates (Dillman et al. 2009). Another way to account for disadvantages is to mix the modes of data collection by including sections using online methods as well as sections using more traditional survey methods (see de Leeuw 2005, for review).

Mechanical Turk

With a large number of researchers utilizing the Internet to collect data, it is important to discuss a

participant recruitment method that is growing in popularity. Amazon Mechanical Turk (MTurk) provides a broad and diverse workforce that allows researchers to obtain data quickly and cheaply. MTurk users, known as “workers” or “turkers,” complete “human intelligence tasks” (HITs) that consist of various tasks for certain amounts of compensation as determined by the source (sometimes even as low as \$.10 per HIT). In order to receive compensation, workers must have their HITs validated such that they are rewarded for high-quality work and penalized for low-quality work. The average worker approximately earns only \$1.40 per hour, much lower than the national minimum wage, but will vary depending on the given task(s) (Horton and Chilton 2010; Ipeirotis 2010).

With such low wages, concerns have been raised in regards to the demographics of the workers on MTurk. Paolacci et al. (2010) collected demographics of approximately 1,000 MTurk workers. In general, workers tended to be more educated and have a lower average income than the general US population. Despite this, Paolacci et al. pointed out that the workers were still closer to the general population when compared to the convenience samples of college students. Other studies have shown that workers tend to be more ethnically diverse than traditional samples but still show a higher proportion of female users that is consistent with other methods (Berinsky et al. 2012). One major benefit of this diversity is the opportunity to recruit workers with particular demographics that may be more difficult to do in a less diverse local environment.

The characteristics of MTurk workers also tend to show a similarity to traditional samples of college students, but there are some important differences to note. In regards to personality traits, workers are less extroverted, have lower self-esteem, and are more socially unstable than traditional samples (Goodman et al. 2013). The cognitive capabilities of workers are more similar to traditional samples, but some evidence has shown that they may have a tendency to be more

risk averse, but the differences are slight (Paolacci et al. 2010; Goodman et al. 2013). In general, MTurk workers are seen as a valid recruitment method to study a variety of topics.

Tips for Conducting Online Studies

In general, online studies benefit from the same guidelines as surveys and questionnaires in regards to response bias (see the Surveys and Questionnaires and Response Bias sections in this book). Alternatively, there are certain aspects of online studies in particular that require careful consideration. First, the informed consent and debriefing information presented should have some method to ensure that the information has been read. For example, researchers could include a time delay before participants can continue the study. In relation, an important aspect of online studies is ensuring that the participants are attentive to the tasks given to them. Providing attention checks throughout the task(s) will allow for poor-quality participants to be parsed from the sample. Although MTurk workers tend to be more reliable in terms of attention, it is a necessary measure of participant quality for all online studies (Hauser and Schwarz 2016). It is also beneficial to record the time it takes a participant to complete the task(s) given to them. Specifically when using MTurk, researchers can set the percentage of HITs the workers have successfully completed in the past. This is often set at 90 % to ensure high-quality participants (Mason and Suri 2012). Lastly, checks should be in place to ensure that the target population is appropriately being sampled by excluding those that do not match the demographics of the target population (e.g., age, language, occupation).

Conclusion

Online studies provide a unique opportunity for researchers to obtain broader samples, conduct

quick and inexpensive research, and utilize unconventional stimuli compared to traditional survey methods. While they have unique benefits, researchers also need to account for the unique challenges associated with an online environment. When used correctly, online surveys provide a novel method which can benefit both the researcher and participant.

Ontogenetic Adaptations

David F. Bjorklund
Department of Psychology, Florida Atlantic
University, Boca Raton, FL, USA

Synonyms

[Transient ontogenetic adaptation](#)

Definition

Ontogenetic adaptations are adaptations that serve an adaptive function at a specific time in development and disappear when they are no longer functional. Examples of ontogenetic adaptations are provided from the prenatal (e.g., placenta in mammals), infancy (e.g., nursing and rooting reflex; neonatal imitation), and childhood (e.g., overestimation of one's abilities, egocentricity) periods. Ontogenetic adaptations provide a mechanism for understanding how certain aspects of early life may have evolved to adapt the young organism to its particular time in development.

Introduction

Evolutionary developmental psychologists have identified three general types of adaptations characteristic of infancy and childhood.

Deferred adaptations serve to prepare infants and children for life as an adult or for the acquisition of important skills that will be useful throughout life. Related to deferred adaptations are *conditional adaptations*, in which current conditions serve as a cue to future environments, with children adjusting aspects of their development in anticipation of future context. Finally, *ontogenetic adaptations* (Bjorklund 1997; Oppenheim 1981) serve primarily to adapt the infant or child to their current developmental niche and are the focus of this entry.

Ontogenetic Adaptations of the Prenatal Period and Infancy

Ontogenetic adaptations are neurobehavioral characteristics that serve an adaptive function at a specific time in development, disappearing when they are no longer needed. Such adaptations are not simply incomplete versions of adult functions but evolved to deal with a specific problem associated with infancy or youth. The most easily identified ontogenetic adaptations are associated with prenatal development. For example, in mammals the placenta and the umbilical cord serve to transport nutrients to and rid waste from the fetus, but they are discarded after birth as infants' entire respiratory and consummatory systems become reorganized.

In humans, many infantile reflexes can be viewed as ontogenetic adaptations. For instance, the *sucking reflex*, activated when the lips or adjacent skin is touched, and the *rooting reflex*, which occurs when infants' cheeks are stroked and they turn their heads and open their mouths in the direction of the stimulation, are adaptive in nursing. The *swimming reflex*, the *palmar grasping reflex*, in which infants grasp objects pressed in the palms of their hands, and the *Moro reflex*, in which infants bring their arms forward as if to hold onto something in response to a loss of support, each have potential survival value and each disappear by 6 months of age or earlier, as control of motor behavior shifts from subcortical to cortical areas of the brain.

Neonatal imitation, in which infants match certain facial gestures of a model (e.g., tongue protrusion, lip pursing), has been proposed not to be a "true" form of social learning, as originally suggested by its discoverers Meltzoff and Moore (1977), but as an ontogenetic adaptation, designed to foster infant–mother interaction at a time in development when infants have little intentional control over their own behavior (Bjorklund 1987). Support for this interpretation comes from evidence that such matching behavior decreases to chance levels by 2 months of age, that infant–mother social interaction is positively associated with previous levels of neonatal imitation, and that such imitation is associated with subcortical brain areas, unlike the "true" imitation observed in children and adults (Nagy 2006).

Several researchers have proposed that infants' memory abilities are especially adapted to the niche of infancy (Bjorklund and Sellers 2014). For example, because of infants' nearly complete dependence on adults, they should be especially attentive to recurring events in their social world. Young infants' memories are also tightly tied to context, which, coupled with their poor inhibitory abilities, prevents babies from retrieving memories in "inappropriate" situations.

Another adaptive characteristic of infancy that promotes survival is "looking cute." The ethologist Konrad Lorenz (1943) long ago noted how immature facial features (e.g., large head relative to the rest of the body, large eyes, small flat nose) of many species promote caregiving. Adult humans find these features endearing and rate infants with these traits as more sociable, easier to care for, more likely to be adopted, and display greater empathy and careful fine-motor behavior as a result of viewing photos of "cute" infants. Adults tend to view infant- or child-like facial features positively relative to the faces of adults and older children until children are about 5 years of age. However, adults continue to view some types of children's *immature cognition* (e.g., "The sun's not out because it's mad") positively (more so than immature facial features; Hernández-Blasi et al. 2015), suggesting that ontogenetic adaptations are also found past infancy into childhood.

Ontogenetic Adaptations of Childhood

Another example of an ontogenetic adaptation in childhood is children's tendencies to overestimate their abilities. Preschool- and early school-age children have an overly positive impression of themselves – they believe they are stronger, smarter, better looking, and more popular than is typically warranted by more objective measures. Such optimistic impressions are not due to poor general cognitive skills. Children are usually able to provide accurate assessments of other children's abilities; their unrealistic assessments are typically limited to themselves (Bjorklund 1997). Such overestimation has been linked to enhanced *self-efficacy*. If young children were aware of how limited their abilities were, they would be less likely to persist at these task, which typically results in improved performance. Support for this comes from studies that report that 3- and 4-year-old preschool children who overestimated their imitation abilities had greater verbal IQ scores than more accurate children (the effect disappeared by age 5) (Bjorklund et al. 1993) and that kindergarten, first-, and second-grade children who overestimated how many words they had recalled on early trials of a memory task had higher levels of memory and strategy performance on later trials than more accurate children (Shin et al. 2007). With respect to memory, young children's tendency to spontaneously reference events and objects to themselves (egocentricity) may enhance their likelihood of later remembering information (Bjorklund and Sellers 2014).

Conclusion

Ontogenetic adaptations provide a mechanism for understanding how certain aspects of early life may have evolved to adapt the young organism to its particular time in development. The presence of such adaptations also causes one to consider that many aspects of infancy and childhood may not simply be unfinished forms of adult functions or as preparation for adult life. Rather, many of the characteristics of infancy and childhood that are considered “immature” may have specific,

evolved functions of their own, and we should be reluctant to speed children through a childhood that has important functions itself.

Ontogenetic Versus Deferred Adaptations

Carlos Hernández Blasi

Department of Psychology, Universitat Jaume I,
Castellón, Spain

Synonyms

Transient vs. non-transient ontogenetic adaptations

Definition

An *ontogenetic adaptation* is a successful solution for a recurrent problem at a specific moment of development in the evolutionary history of a species that disappears once the problem has been solved. Examples are the placenta and umbilical cord in mammals. On the other hand, a *deferred adaptation* is a solution selected through the course of evolution, not just for solving a specific adaptive problem at a certain time in development, but also to prepare developing animals for their future life as adults. This would be the case of play in humans, and for many other species.

Introduction

An adaptation is a solution to a significant, recurrent problem of a species shaped by natural selection over time. As Darwin recognized (1868), adaptations have been shaped not only to solve problems of adult members of species (survival, mating, parenting and kinship, group living), but also problems of immature members of species at different stages of development. From an evolutionary developmental perspective, development can be compared with a bridge that connects two shores: conception and reproductive age (Bjorklund et al. 2016), whose length varies among species, and whose crossing is mandatory for adults aiming to reproduce themselves. In this context, ontogenetic and deferred adaptations are adaptations that respectively solve specific

problems of the developing members of a species (ontogenetic adaptations), and/or prepare them for adulthood (deferred adaptations).

Ontogenetic Adaptations

Immature developmental features in most species have been typically seen only as antecedents or basis for future adults' behaviors, and not as traits that can accomplish, by themselves, a certain function at a specific developmental moment (Hall and Oppenheim 1987). An ontogenetic adaptation is an evolutionary solution for a recurrent problem at a specific time in development that, once solved, disappears. In a sense, an ontogenetic adaptation is a disposable adaptation. This would be the case, for example, of hatching mechanisms in eggs-laying animals, placenta and umbilical cord in mammals, and many infantile reflexes, such as the sucking, rooting, and palmar-grasping reflexes. The first contemporary use of this concept in both developmental psychobiology and developmental psychology is attributable respectively to Oppenheim (1981) and Bjorklund (1997), although other authors (e.g., Baldwin, Werner) had referred to it, either explicitly or implicitly, earlier in the twentieth century.

Ontogenetic adaptations can be found at different levels (e.g., morphological, physiological, and behavioral) and at different developmental stages (e.g., prenatal period, infancy, and childhood in humans), although they are more easily seen when some drastic environmental changes take place. This would be the case, for example, of an amphibian metamorphosis, switching from living in an aquatic to a terrestrial environment, and therefore generating temporary adaptations for their temporary conditions (e.g., respiratory mechanisms such as gills while living in the aquatic milieu), or for a species whose prenatal and postnatal environments are quite different in nature, as in mammals and birds.

In humans, as well as in other altricial species (i.e., species whose offspring exhibit a high degree of motor, sensory, and/or social immaturity at birth or soon after hatching), many early postnatal ontogenetic adaptations have to do with catching adults' attention and/or guaranteeing

adult support at a time of extreme vulnerability and dependence. This would be the case, for example, of attachment behaviors such as smiling, crying, or raising arms toward an adult, or the “looking cute” *baby-schema* thoroughly described by ethologist Konrad Lorenz (1943). Importantly, these types of adaptation often require corresponding and simultaneous adaptations in adults: attachment behaviors or infants’ physical appearance would not have such effects if adults were not also notably sensitive and responsive to these kind of immaturity cues.

Deferred Adaptations

The concept of deferred adaptation was coined by Hernández Blasi and Bjorklund (2003), although it was already implicit in Oppenheim’s work, who pointed out that “in many cases ontogenetic events may serve immediate needs, as well as influence future goals” (Oppenheim 1981, p. 75), in a way that “the behavior exhibited by developing animals reflect a balance between meeting the needs of the moment and preparing for later life” (Hall and Oppenheim 1987, p. 95). This rationale seems to suggest that “in most instances ontogenetic adaptations may serve both immediate *and* future needs” (Oppenheim 1981, p. 99), and this is what deferred adaptations are all about. Namely, a deferred adaptation is an evolutionary efficient solution to a recurring significant problem of a species member at a certain time in development that *simultaneously* prepares the developing animal for adulthood.

Play is a good example of deferred adaptation in humans (as well as in other species), as it clearly helps children to both understand some critical issues of their immediate sociocognitive environment, and at the same time to understand the nuances of the world they will live in as adults (see e.g., Pellegrini and Bjorklund 2004, for an evolutionary analyses of both object and fantasy play in children). Theory of Mind might be also a good candidate for deferred adaptation. This is an important mechanism for social relationships, available when young children are approximately

about 4/5 years old (Perner et al. 1987), that makes it possible to “read others’ minds,” that is, to understand people as mental beings whose mental states (e.g., thoughts, beliefs, motives, feelings) can explain and predict their own and others’ behavior. This ability permits children to adapt to the increasingly out-of-family social world that follows in most of traditional societies after weaning (typically at 3 years, Dettwyler 1995), at the same time that it prepares them for their future social roles as adults by learning about other people’s mind and what motivates their actions.

It is important to note that deferred adaptations do not implicate the existence of an anticipated plan by natural selection, as, obviously, as far as we know, natural selection operates on the here-and-now basis. Quite probably, deferred adaptations functioned initially as ontogenetic adaptations, but instead of disappearing, as happens with *true* ontogenetic adaptations, they continue operating throughout life. This is more apt to occur when environmental characteristics during the developmental period in which they emerge and in adulthood are similar (Hernández Blasi and Bjorklund 2003).

Conclusion

Natural selection operates not only during adult life but also across development. Ontogenetic adaptations provide specific solutions to recurrent problems at specific moments in the development of a species and then disappear when they are no longer needed. In this sense, they are immediate, transient, and provisional adaptations. In contrast, deferred adaptations afford developing individuals not only immediate benefits in terms of skills and/or knowledge, but also delayed benefits that extend into adulthood. In this sense, they are nontransient, permanent, and anticipatory adaptations.

We do not have available a complete catalogue of ontogenetic and deferred adaptations in humans yet (nor a catalogue of epiphenomena, such as, for example, the belly button as

contrasted with the umbilical cord; not everything in development is an adaptation). Therefore, the determination of which behaviors contribute to adaptive outcomes (or might have contributed to adaptive outcomes in the *environment of evolutionary adaptedness*), and how – either to solve children’s adaptive problems at a specific time in development or to prepare children for their lives as adults – constitutes both a necessary and exciting challenge for understanding better the nature of human development and its evolution.

Definition

In behavioral learning theory, operant conditioning is defined as a learning process in which the likelihood of a specific voluntary behavior is strengthened (increases in frequency) or weakened (decreases in frequency) in response to consequences (reinforcement or punishment, respectively), occurring after the behavior is exhibited.

Introduction

Operant conditioning is a learning process appearing in behavioral learning theory. According to the theory, the likelihood of a specific voluntary behavior is strengthened (increases in frequency) or weakened (decreases in frequency) in response to the consequences (reinforcement or punishment, respectively) that follow the behavior. Whereas classical conditioning is used to re-train reflex behaviors (e.g., crying when we feel afraid, salivating when we smell food) so that they appear under new conditions (in the presence of a conditioned stimulus, not only of an unconditioned stimulus that requires no prior learning), operant conditioning is used to produce behaviors that are not part of one's repertoire of reflex behaviors (i.e., they are "new" behaviors). The major theorists in the area of operant conditioning are Edward Thorndike and B. F. Skinner, who maintained an experimental approach to the study of learning. Findings from learning experiments with animals in the laboratory were extrapolated to human learning as they maintained that fundamental principles of learning apply to learning across species (equipotentiality).

Overview of Operant Conditioning

Operant conditioning is based on Thorndike's Law of Effect (Thorndike 1898, 1911) that stated that responses to a situation that are followed by satisfaction are strengthened, whereas responses that are followed by discomfort are weakened

(Ormrod 2016). The term operant conditioning (Skinner 1937) derives from the idea that organisms learn to "operate" on their environment (i.e., produce a particular behavior) in order to receive or avoid a particular consequence (Snowman and McCown 2012). The term "conditioning" (as opposed to learning) is used by behaviorists to denote that learning happens in a way that is beyond one's control as it is dependent upon individual experience (i.e., an organism is conditioned to behave in a certain way as a response to environmental stimuli) and thus one might argue that it focuses on a deterministic nature of learning.

Learning in the context of operant conditioning has originally been described using a Response-Stimulus pattern. More recently, a three-term model (Stimulus-Response-Stimulus) has been used (Huitt and Hummel 1997). The main premise is that a response is preceded by an environmental event (also known as antecedent stimulus) and is also followed by a stimulus (also known as consequence), which determines whether the behavioral response is more or less likely to occur in the future. A pleasant consequence (reward) increases the probability of a behavior occurring in the future, while an aversive consequence (punishment) decreases the probability of the behavior being repeated.

The Work of B. F. Skinner

Skinner has been named as the most eminent psychologist of the twentieth century (American Psychological Association 2002) for his work on operant conditioning through which he showed that behavior can be shaped through reward and punishment. Animal behavior in the laboratory was studied using the operant conditioning chamber (also known as Skinner box), developed by Skinner himself. With this device, Skinner was able to observe and quantify the behavior of animals (e.g., rats, pigeons) interacting with the environment. Through his observations, he formulated the basic principle of operant conditioning: A behavior followed by a reinforcer is strengthened and is therefore more likely to occur again

(Skinner 1938) – in other words, reinforcement results in learning. Skinner was able to observe that an animal inside the Skinner box, initially through trial and error as they moved about the box, at some point engaged in a behavior that produces a pleasant consequence (i.e., is reinforcing) such as receiving a pellet of food when pressing a lever. Repetition of this pattern response-consequence pattern over time resulted in the animal forming an association between the behavior and its pleasurable consequence. The desire for receiving the reward acts as a motivator for the animal to continue to engage in that behavior and consequently the behavior increases in frequency (behavior strengthened). In an analogous manner, behavior that was followed by punishment (such as a mini electric shock) eventually decreased in frequency (behavior weakened). Some of his major contributions were: the investigation of intermittent patterns schedules of reinforcement and their effect on speed of learning and extinction of behavior (Ferster and Skinner (1957), the concept of behavior shaping through successive approximation (Skinner 1951), modification of behavior using principles of operant conditioning (Skinner 1938, 1953), the chaining of complex behavioral sequences via secondary reinforcers (Skinner 1938), and the development of superstitious behavior (Skinner 1948).

Necessary Conditions for Learning

Contiguity

Skinner highlighted the importance of *temporal contiguity* in forming the associations necessary for operant conditioning to take place. More specifically, he stated that “to say that a reinforcement is contingent upon a response may mean nothing more than that it follows the response. It may follow because of some mechanical connection or because of the mediation of another organism; but conditioning takes place presumably because of the temporal relation only, expressed in terms of the order and proximity of response and reinforcement” (Skinner 1948, p. 168).

The process of operant conditioning is very sensitive to temporal relations. For learning to

take place under the paradigm of operant conditioning, it is imperative that three conditions are met (Ormrod 2016):

- (i) The reinforcer must follow the response: The reward should appear after the target behavior takes place, it should not precede it as it is then less likely that the organism will associate the presence of the reinforcer with a specific behavior.
- (ii) The reinforcer must follow immediately: Delayed reinforcement is less effective because other environmental events or behavioral responses that may take place in between will constitute the formation of the association between the reinforcer and the target behavior more difficult as they intervene.
- (iii) The reinforcer must be contingent (conditional) on the response: A reward should only be presented when a desired behavior has occurred so that a direct link is made between the two.

Discrepancy

In order for an organism to make the association between environmental event (reinforcement) and action (behavior), the produced behavior must be discrete from already exhibited behaviors. *Behavioral discrepancy*, defined as the difference between an ongoing and an elicited behavior (Donahoe 2003; Donahoe and Palmer 1994) is a necessary condition. A reinforcer must not only be presented immediately after the behavior in order for the association to be made, but it must also induce a response that is not already occurring (Kamin 1969).

Principles of Operant Conditioning

In the laboratory, Skinner refined the concept of operant conditioning and the Law of Effect. Among his contributions were the investigation of how different forms of reinforcement and punishment affect evidenced behavior, a systematic exploration of intermittent schedules of reinforcement, the shaping of novel behavior through

successive approximations, the chaining of complex behavioral sequences via secondary (learned) reinforcers, and “superstitious” (accidentally reinforced) behavior. These major contributions are further discussed below.

Consequences and Contingencies in Operant Conditioning: Reinforcement and Punishment

Skinner (1938) identified three different types of operants that can affect behavior following conditioning: Neutral operants (no effect on frequency of exhibited behavior), reinforcers (increase frequency of behavior), and punishers (decrease frequency of behavior).

Reinforcement is defined as an environmental stimulus that results in an increase of the frequency of an exhibited behavior because the organism, after a number of contiguous presentations of behavior-reward, associates a specific behavioral action with a desired outcome. Reinforcement can be positive or negative, depending on whether a pleasant stimulus is added (positive) or an unpleasant one is removed (negative). Positive Reinforcement involves the presentation of a stimulus that increases the occurrence of a behavior (e.g., the presentation of food after the mouse presses the lever in Skinner’s experiments). Negative Reinforcement entails an increase of behavior because it results in the removal of an aversive stimulus (e.g., a person takes aspirin to treat their unpleasant headache).

Punishment has the opposite effect. A decrease in frequency of a particular behavior because it is associated with an unpleasant outcome. In Positive Punishment (also known as Punishment I), a particular behavior is followed by a presentation of an unpleasant stimulus (e.g., an electric shock in Skinner’s experiments). In Negative Punishment (also known as Punishment II or Response Cost), a pleasant stimulus is removed (e.g., a child is sent to bed without dinner following naughty behavior).

Schedules of Reinforcement

Continuous reinforcement (receiving reinforcement every time a particular behavior is exhibited) results in faster learning (fast response rate) as the organism can relatively quickly make the

association between behavior and outcome when the reinforcement for a new behavior is given every time it is exhibited. What happens if reinforcement is not continuous, i.e., it is not given consistently? In the case of previously continuous reinforcement, removal of reinforcement results in fast extinction. Ferster and Skinner (1957) found that different schedules of reinforcement (continuous, ratio and interval) alter the speed of learning (response rate) and extinction (cease of a behavior). They experimented with fixed (regular) and variable (unpredictable) modes of presenting ratio and interval schedules of reinforcement.

In ratio reinforcement schedules, responses are reinforced on the basis of the number of responses exhibited by the organism. A *fixed ratio schedule* is one where a reinforcer is presented after a certain number of responses is displayed (e.g., after 10 responses). This type of schedule produces a high rate of response followed by a short postreinforcement pause (Ferster and Skinner 1957; Powell et al. 2017). The extinction rate following nonreinforcement of a previously reinforced response depends on the schedule of reinforcement applied to maintain that behavior. Resistance to extinction is higher the less frequent the reinforcement previously received, a phenomenon known as partial reinforcement effect (Mowrer and Jones 1945). More recent experiments have replicated these findings, as rats that were given continuous reinforcement extinguished the previously reinforced response of approaching a goal location in a water maze sooner than those previously given partial reinforcement (Prados et al. 2008). In a *variable ratio schedule*, reinforcement is presented after a varying and unpredictable number of responses and is determined by the average number of responses needed to receive a reward (e.g., a slot machine). This type of schedule results in a high response rate, with little or no postreinforcement pause (Powell et al. 2017) and is highly resistant to extinction following cease of reinforcement (Ormrod 2016) because the unpredictability of the reinforcement makes the realization of the cease of its presentation more difficult. When behavior has been maintained on a variable ratio schedule, it is usually more resistant to

extinction compared to a fixed ratio schedule (Reynolds 1975).

In interval schedules, the presentation of reinforcement depends on the time interval elapsed – the reward is presented following the exhibition of the first desired response after an amount of time has passed. A *fixed interval schedule* is one where reinforcement is contingent upon the first response after a predetermined and predictable time interval (e.g., after 5 min). Research shows that this type of reinforcement schedule results in a “scalloped” (curved upwards) response pattern. It involves a postreinforcement pause followed by a gradual response rate increase as the time interval is nearing completion (Powell et al. 2017). Response rate in this type of schedule is medium (a lower rate is observed compared to a fixed ratio schedule), and it is also less resistant to extinction (Ormrod 2016). In a *variable interval schedule*, the time interval elapsed for the presentation of reinforcement is less predictable as it depends on an average interval over a time period rather than a fixed one. This unpredictability results in a moderate and steady rate of response with little or no postreinforcement pause (Powell et al. 2017) and has greater resistance to extinction (Ormrod 2016).

Figure 1 summarizes response rates according to schedule of reinforcement applied (Huitt and Hummel 1997). The hatch marks on each line on the graph denote the presentation of a reinforcer.

Operant Conditioning, Fig. 1 Schedules of reinforcement and response rate (Huitt and Hummel 1997)

Shaping

Shaping (Skinner 1951) is a process where successive approximations of a behavior are reinforced, resulting in a gradual generation of the desired response (Powell et al. 2017). Successively closer approximations of a behavior are being rewarded until the organism succeeds in exhibiting the desired response (terminal behavior). This technique can be used to facilitate the demonstration of a particular response when an organism either lacks the skill or is not inclined to perform a desired behavior. Shaping can successfully be used in the process of learning a complex behavior or skill and has therefore useful applications in education (Snowman and McCown 2012). By reinforcing, gradually increasing in complexity behaviors that resemble the desired outcome and ignoring those that do not, a person gradually develops the necessary skills and moves closer to completing a complex task.

Chaining

A chain, according to Skinner (1953) is created when a response produces or alters some of the variables, which control another response. Complex behaviors, such as a sequence or chain, can be learned through the process of shaping. Chaining is a process where initially one response is reinforced, then two successive responses are reinforced, then a chain of three responses and so on (Ormrod 2016). Chaining establishes “*complex behaviors made up of discrete, simpler behaviours already known to the learner*” (Driscoll 2000). A *chained schedule* consists of a sequence of two or more simple schedules, each of which has its own discriminative stimulus, with the last in the sequence resulting in a terminal reinforcer (Powell et al. 2017). The majority of human endeavors consist of long response chains and in such cases where the terminal reinforcer is temporally distant (e.g., completing a Masters program), retaining the motivation to complete the chain can be quite a challenge. One way to deal with this is to identify the various links in the chain (e.g., the different courses) and the completion of each link to be made more prominent (for example, through self-reward, feelings of

satisfaction, etc.) so that it acts as a secondary reinforcer for the next part of the chain (Powell et al. 2017).

Superstitious Behavior

When a reinforcement is administered in a random fashion, it can result in superstitious behavior (Skinner 1948). When the organism receives reinforcement, it naturally assumes that it relates to its immediately preceding behavior, even though it may be unrelated. As a result, an incorrect connection between behavior and response is made (Ormrod 2016), and a behavior is “accidentally” reinforced. As stated by Skinner (1948, p. 168), “whenever we present a state of affairs which is known to be reinforcing at a given drive, we must suppose that conditioning takes place, even though we have paid no attention to the behavior of the organism in making the presentation.”

Applications of Operant Conditioning

Behavior Modification

Principles of operant conditioning have effectively been used in behavior modification for two main purposes: To *strengthen desired behaviors* (mainly through reinforcement) and to *weaken or eliminate undesired behaviors* (mainly through the ceasing of previous reinforcement or use of punishment).

Reinforcement, through rewards, has extensively been used to increase desired behaviors and is a particularly effective technique in educational settings. The methods of *shaping*, *token economy*, and *contingency contracting* have effectively been used.

According to Alberto and Troutman (2009) and Miltenberger (2008), the following steps should be followed in order to successfully achieve *shaping* of target behaviors in the classroom:

- (i) Identify target desired behavior
- (ii) Obtain baseline data by determining the anticipated frequency of target behavior’s occurrence
- (iii) Select reinforcers to be used

- (iv) Reinforce successive approximations of target behavior when it occurs
- (v) Reinforce target behavior when exhibited
- (vi) Reinforce target behavior using a variable reinforcement schedule

One of the major challenges of applying reinforcement in a classroom context that is comprised of a number of individuals is to identify a reward that will be reinforcing for every member of the group. What is reinforcing to one individual, may not be for someone else. For example, a piece of chocolate may be an effective reinforcer for one child but not for another who happens to be lactose intolerant. One method that can be used to overcome this challenge is the use of *token economy*. With this method, individuals “earn” tokens in the form of stars, coupons, plastic coins, etc. for evidencing desired behaviors, completing academic tasks, completing chores, etc. that can be accumulated and later be exchanged for “individualized” reinforcers (reinforcers individually chosen on the basis of interests and likes).

Drawing a *contingency contract*, a formal agreement specifying the target desired behaviors and the outcome of exhibiting those behaviors (i.e., the rewards to be received) is an effective way to communicate expectations and consequences concretely. Such contracts can be written or verbal and both parties (e.g., parent-child or teacher-child) should agree to it.

It is worth noting some challenges in the application of operant conditioning for the purposes of strengthening desired behaviors. Human learning is a complex process, and reinforcement alone may not always be effective when cognitive factors are not taken into account. For example, when the acquisition of a new skill is negatively affected by cognitive deficiencies, simple reinforcement will not produce the desired effects (Ormrod 2016). Furthermore, constantly reinforcing behavior can interfere with long-term learning and performance. Extrinsic reinforcement can make individuals susceptible to focus on the product and not on the process of learning (Ormrod 2016). Finally, extrinsic reinforcement of an enjoyable activity or task can weaken its

intrinsic value as individuals focus on the reward to be earned and are more likely to lose interest when it is taken away (Ormrod 2016).

Principles of operant conditioning can also be used to weaken or eliminate undesired behaviors, through the methods of extinction, negative punishment (time-out and response cost), and positive punishment.

Extinction is the elimination of an undesired behavior, and it is achieved through nonreinforcement of a previously reinforced response (Powell et al. 2017). At the initial stages of implementing this method, one may observe a variety of side effects, including extinction bursts (brief increase of the frequency of the undesired behavior; Lerman and Iwata 1995; McGill 1999), emotional behavior (Zeiler 1971), aggression (Azrin et al. 1966), and depression (Klinger et al. 1974).

Time-out and *response cost* are types of negative punishment as they consist of the loss of a privilege or a positive reinforcer for a brief period of time after the individual evidences undesired or problem behavior (Powell et al. 2017). *Time-out* involves asking the individual exhibiting problem behavior to stay in a specified setting that does not include reinforcers for a few minutes. This location should not include reinforcers and the time-out period should be brief. According to Miltenberger (2008), a time-out period of 1 min may be enough to effectively eliminate the undesired behavior. The key is to immediately reinforce more appropriate behaviors as soon as the individual returns to the normal setting. *Response cost*, involves the removal of a previously earned reinforce, following the occurrence of a problem behavior. According to Powell et al. (2017), an advantage of response cost is that one can easily adjust the severity of the punishment according to the degree of severity of the problem behavior.

Positive punishment consists of the presentation of a certain undesirable event to the individual (e.g., reprimanded by a parent, going to detention) following a problem behavior, which on the basis of operant conditioning principles leads to a decrease in frequency of the specific behavior. The use of punishment is advised when

the undesired behavior can harm oneself or others and can produce quick results (Ormrod 2016). In such context, it is imperative that the reasoning behind the specific behavior considered to be unacceptable and a justification of punishment is communicated clearly, as well as consistency in the delivery of punishment (Ormrod 2016). Various problems have been identified with the use of punishment, and so it should be used very cautiously. These include the elicitation of strong emotional responses, aggression, avoidance behavior, and the individual resorting in the use of punishment to modify others' behavior through the processes of modeling (Powell et al. 2017). Physical punishment should be avoided, as it provides the individual with a model of aggression that can be imitated at a later stage as it gives the message that aggression is an acceptable form of behavior (Landrum and Kauffman 2006). Psychological punishment, such as insulting comments or public humiliation, should also be avoided as it can have negative effects on emotional well-being and self-perceptions (Walker and Shea 1995).

Applied Behavior Analysis (ABA)

Applied Behavior Analysis (ABA) has been defined as a science in which systematic applications of principles of the analysis of behavior in order to improve socially significant behavior, using experimentation to identify the variables responsible for behavior change (Cooper et al. 2007). It is comprised of systematic description and implementation of a therapeutic intervention to change an undesirable or problem behavior, on the basis of the principles of behaviorism (Sulzer-Azaroff and Mayer 1991). According to Baer et al. (1968), an applied analysis of behavior highlights: the importance of the behavior changed, its quantitative characteristics, the experimental manipulations responsible for the change, the technologically exact description of the procedures leading to the observed change, the effectiveness of those procedures in making the change sufficiently valuable, and the generality of the change.

Skinner's operant conditioning theory contributed significantly to the birth of Applied Behavior

Analysis (Morris et al. 2005) and Skinner's (1938) three-term contingency model (S-R-S) can be a useful analytic tool. It is more commonly known in this context as the A-B-C model. In this process, the teacher or therapist collects information about (1) the target behavior and (2) the *Antecedents-Behavior-Consequences* (A-B-C). Antecedents include features of the environment immediately prior to a person producing a particular behavior. Behavior is the manifested response, and consequences are the events or outcomes that follow the behavior.

When the ABA method is applied in education contexts, it can be used to teach appropriate behaviors that involve breaking tasks into small, discrete "teachable" steps. At each step, appropriate behaviors are reinforced. Teaching targets are developmentally appropriate behaviors, and the child is given enough support to ensure success (thus ensuring the receipt of positive reinforcement). Gradually, the amount of support and reinforcement is reduced, while the behavior is monitored until the child is able to complete the task unaided. The behavior is closely observed, both before and during the intervention phase (Daly et al. 2009). ABA has been applied successfully in classroom settings for children with learning difficulties who evidence disruptive behavior (Jones and Kazdin 1975), as well as early intervention programs for children with learning difficulties. In such early intervention programs, parents are often trained to become the primary therapists (giving children one-to-one tuition at home), an approach that has been shown to be an effective intervention in helping children with autism to be more successful in mainstream schools (Keenan et al. 2000).

Evolutionary Perspectives on Operant Conditioning

Evolutionary psychology and behaviorism both attempt to understand human behavior in a scientific paradigm, and it has been argued that there is possibility of greater convergence than previously thought between the two theoretical orientations (Genovese 2007). Skinner, in fact, had considered the idea that genes and natural selection shape

behavior in his work (Skinner 1953) and had stated that "the behavior of organisms is a single field in which both phylogeny and ontogeny must be taken into account" (Skinner 1977, p. 1012). Learning could be considered as an evolutionary adaptive behavior, a capacity supporting the formation of predictions in unpredictable environments (Dawkins 1976), thus facilitating adaptation and survival. Skinner, had described operant conditioning as selection by consequences (Skinner 1981) and had stated that in a context where an organism adapts its behavior to a given environment and has therefore less need for an innate repertoire of behaviors, "operant conditioning could not only supplement the natural selection of behavior, it could replace it" (p. 501).

Skinner (1974, p. 41) acknowledged that "survival may be said to be contingent upon certain kinds of behavior." He used the examples of mating, protecting self from harm, and caring for one's child. While some of these behaviors are innate mechanisms facilitating survival, contingencies of reinforcement within the environment result in them being preserved through an operant conditioning process. And in cases where changes happen in the environment, operant conditioning principles guide organisms to develop new behaviors so that they continue to obtain reinforcers (Skinner 1974, 1981, 1984).

Conclusion

In behavioral learning theory, operant conditioning attempts to explain human behavior on the basis of a three-contingency model of stimulus-response-stimulus. It has succeeded in describing why some behaviors strengthen and others weaken in response to the consequences (reinforcement and punishment, respectively) that follow. It has a variety of applications in behavior modification, for example, in strengthening desired behaviors (mainly through reinforcement using methods such as shaping, token economy, and contingency contracting) and weakening or eliminating undesired behaviors (mainly through the extinction and punishment). It also has significant applications in educational settings and Applied Behavior Analysis. In the

context of evolutionary psychology, operant conditioning has been described as selection by consequences (Skinner 1981), facilitating adaptation in unpredictable environments.

Operational Sex Ratio

Daniel Kruger
University of Michigan, Ann Arbor, MI, USA

Synonyms

[Mating market](#)

Definition

The ratio of sexually available males to sexually available females in a population.

Introduction

The relative proportions of reproductive males and reproductive females in a population influence reproductive dynamics, including intersexual selection and intra-sexual competition. Across species, market influences of these proportions affect the intensity of mating competition and selectivity for partners. Female-biased (more available women than men) and male-biased (more available men than women) populations produce different outcomes because the reproductive strategies of men and women are somewhat divergent. Imbalanced sex ratios are associated with social and cultural trends in specific historical periods and populations. Male scarcity enhances male mating opportunities and decreases incentives for long-term commitment, facilitating serial and simultaneous polygyny. Female scarcity enhances the ability to secure commitment from partners and demand higher levels of resource investment. Male social power often constrains women's ability to leverage their market scarcity for serial or simultaneous polyandry.

Evolutionary Dynamics

Darwin (1871) recognized that a species' sex ratio was usually nearly balanced between males and females because on average, males and females in a population will have equivalent reproductive success. Each offspring has one female and one male parent. If there are more females in a population than males, a daughters' average reproductive success will be lower, favoring the production of sons. The advantageous production of the rare sex generates a stable equilibrium on an evolutionary time scale; human populations may exhibit imbalanced sex ratios at particular points in time (Darwin 1871). Düsing (1884) and Fisher (1930) created formal mathematical models based on these concepts.

Emlen and Oring (1977) originally defined the operational sex ratio (OSR) as the number of sexually active males per 100 sexually receptive females in a population. An OSR of 100 represents

a sex ratio with balanced proportions of males and females. An OSR below 100 is considered a low sex ratio representing a female-biased population (e.g., more available females than males). An OSR above 100 is considered a high sex ratio representing a male-biased population (e.g., more available males than females). Researchers have operationally defined the human OSR in terms of raw population counts (e.g., Barber 2000) and as the ratio of unmarried adult men to unmarried adult women (e.g., Kruger et al. 2010). Because the reproductive strategies of men and women are somewhat divergent, imbalances in the OSR exhibit directional effects consistent with the strategies of each sex.

Sex Roles in Reproduction

Following the economic patterns of supply and demand, the rare sex is more valuable in the mating market (Fisher 1958). Because men and women have somewhat divergent reproductive strategies, imbalances in the sex ratio have differential effects consistent with the strategies of each sex. Females are the limiting factor in reproduction in most animal and all mammalian species because they provide almost all of the physiological resources required for offspring production. Because of the larger necessary investment required for females, females have much lower potential reproductive capacities than males. Thus, females are more discriminating in selecting mates and males expend comparatively more effort in acquiring and retaining mates (Trivers 1972).

Human preferences for potential romantic or sexual partners in part reflect the differential roles and contributions made by men and women in successful reproduction. Both sexes prefer partners who exhibit characteristics such as kindness, understanding, and intelligence (Buss 1989; Kenrick and Simpson 1997). There is considerable overlap in men and women's criteria for potential partners; however, there is also divergence following reproductively relevant attributes. Although the nonphysiological parental investment that mothers provide is typically

higher than that of fathers, men's parental investment is much larger than that of other male primates (Buss and Schmitt 1993; Geary and Flinn 2001). The importance of father investment is indicated by the effects of their absence; children in foraging populations who grow up without a father present suffer higher mortality rates (Hill and Hurtado 1996). Paternal investment in offspring may enhance the offspring's reproductive success (Geary 2005). In modern populations, investment from fathers promotes positive child outcomes (Lamb 2004) and protects against negative outcomes such as delinquency (Harris 2002).

Women and men actively seek the resources related to reproductive value which men and women provide in reproductive relationships (Kruger 2008). Women provide physiological investment and men typically provide substantial material resource investment. Men seek women with cues of fecundity, the physiological potential for bearing offspring, whereas women prefer men with the ability and willingness to commit to long-term relationships and provide substantial paternal investment (Buss 1989). Men with higher social status and greater resource control have higher reproductive success across a wide variety of societies (Hopcroft 2006).

Male-Biased Sex Ratios

The economics of numerical supply and demand influences what individuals can demand from prospective mates. As the OSR becomes increasingly male biased, males compete more intensely for fewer females. The enhanced power of female choice raises the quality of valued male attributes necessary for securing female partners. There is more competition among men to demonstrate that they would be committed long-term relationship partners and resource providers (Pedersen 1991). Men offer more in a relationship, invest more time to wooing, are more romantic in dyadic interactions, and attempt to demonstrate more potential for resource investment (Guttentag and Secord 1983). Women will expect husbands to be of relatively higher social status, be kind, loving,

and generous and share the responsibilities of parental care (Guttentag and Secord 1983). Men with lower social status and fewer resources have an especially difficult time getting married (Pollet and Nettle 2007).

Women tend to marry at younger ages as they are able to secure male commitment earlier (Kruger et al. 2010). Some men also marry at younger ages as they have more motivation to secure a prospective partner before another man does. However, men also need to acquire greater social status and resources to be considered marriageable, and this can take considerable time and effort. Thus, as the population becomes increasingly male biased, the variance in male marital age increases (Kruger et al. 2010).

Male social power constrains potential female advantages, especially in societies where greater male social power is embedded in legal structures. High sex ratios are associated with greater emphasis on traditional sex roles and norms that both protect and constrain women, though women who can choose their own marriage partners have more power and control (Guttentag and Secord 1983).

Female-Biased Sex Ratios

In populations where women are more numerous than men, women compete more intensely for male partners. The forms of competition reflect attributes related to female mate value that men seek in partners, fecundity and sexual availability (Cunningham 1986; Tesser and Martin 1996). Sexuality and fecundity are emphasized in fashion trends for revealing clothing, such as shorter skirt lengths (Barber 1999; Time Out New York 2007). Women are more self-conscious about their physical appearance and the appearance of other women. Women wear revealing clothing, derogate other women who are wearing revealing clothing, and may even derogate other women for wearing the same fashions that they display themselves (Guttentag and Secord 1983; Time Out New York 2007).

When women are more numerous than men, men have less incentive to provide relationship

commitment and paternal investment (Pedersen 1991). Female-biased sex ratios are associated with higher divorce rates, more out-of-wedlock births and single mother households, and lower paternal investment (Guttentag and Secord 1983; Trent and South 1989). Greater proportions of females are associated with more promiscuous mating strategies across nations (Schmitt 2005).

Polygyny

The higher the degree of polygyny in a population, where high status men are better able to attract and/or retain multiple female partners, the higher the effective sex ratio will be. For every woman who is polygynously mated, there is one less woman available to other men. A polygynous population with a numerical balance of reproductive aged men and women may have an effectively male-biased sex ratio (Hendrix 1996). The degree of polygyny will constrain the effects of female numerical surplus, as well as accentuate male competition in balanced or male-biased populations. Higher degrees of polygyny are associated with greater consequences of male mating competition (Kruger 2010).

Conclusion

The operational sex ratio is a powerful influence on humans and other species. The more numerous sex faces greater intra-sexual competition for partners, and the scarce sex has greater power to select partners with desirable attributes, increasing the intensity of intersexual selection. Biased sex ratios exhibit patterns consistent with the divergent reproductive strategies of each sex. Men leverage their market scarcity for greater sexual access while avoiding long-term relationship commitments. Women are able to marry at earlier ages and obtain greater investment when scarce, although they are often constrained by social structures benefitting the reproductive interests of males.

Synonyms

Cross sex friend; Opposite-gender friend

Definition

Unrelated person of the opposite sex for whom one feels affection or esteem.

Introduction

Opposite-sex friendship is a historically novel relationship between a man and a woman that is supposed to be platonic and nonsexual. Evolutionary psychology considers opposite-sex friendships through two perspectives: as a specific type of friendship that has its own psychological adaptations and as a type of relationship “ruled” by mating strategies used in an evolutionary novel social situation. Considering sexual attraction is often experienced in this type of relationship, existing research mostly confirms the second perspective.

Historical and Social Context

Opposite-sex friendships are relationships between men and women that present a fairly new development in social relations and have only recently become a subject of research.

Additionally, opposite-sex friends are less common than same-sex friends. Historically, having an opposite-sex friend has been quite unusual, as men-women relationships have mostly been seen through the perspective of romantic partnership. For example, in the 1950s, it was extremely rare for men and women to have an opposite-sex friend, compared to now when people report having more than one opposite-sex friend. In that period, social structure and norms have separated women and men through different social roles they were fulfilling, and, aside from relatives and spouses, neither women nor men were able to develop more significant relationships with the opposite sex. The modern way of life has made it possible for men and women to spend time together, at work and in other social activities, which makes it possible to form opposite-sex relationships which are not focused solely on romantic motives or sex (Bleske-Rechek et al. 2012; Halatsis and Christakis 2009).

Evolutionary Psychology and Opposite-Sex Friends

Evolutionary psychology has viewed opposite-sex friendships as relationships that had existed in the evolutionary past and therefore caused the development of specific psychological adaptations, in order to manage such friendships (Bleske and Buss 2000; Buss 2008). As Bleske-Rechek et al. (2012) mention, this perspective would have required a regular interaction with opposite-sex friend(s) that would have helped our ancestors with two basic evolutionary problems: survival and reproduction. Essentially, that would mean opposite-sex friends helped our ancestors in their everyday survival, through sharing food and shelter and providing physical protection or sexual access, in such a way that enabled a higher survival rate and reproduction for individuals in such friendships.

A different perspective proposes that perceptions of the opposite-sex friend are by-products of mating strategies being used in a new evolutionary environment – the so-called by-product hypothesis (Bleske-Rechek et al. 2012). More specifically, the

attraction experienced in opposite-sex friendships is a manifestation of activated mating strategies applied to novel social situations, in which a person is in contact with numerous unrelated opposite-sex individuals. As previously mentioned, opposite-sex friendships are a historical novelty, as our ancestors were foragers and nomads that lived in small groups consisting of reproductive partners and kin, and it seems highly unlikely individuals had an opportunity to develop nonsexual supportive relationship with the opposite sex (Bleske-Rechek et al. 2012).

Mating strategies are psychological adaptations for partner selection which are sex specific due to the amount of resources invested in offspring, as proposed by Trivers (1972) in his well-known *Theory of parental investment*. Multiple research has proven the premises of the theory: men consider signals of fertility, youth, and health in a partner and have preferences toward a variety of partners, compared to women who are more discerning and looking for signals of good parenting and partnership, as well as efficient provision of food and other goods (Buss 2008). Considering opposite-sex friendship in this context, research has shown opposite-sex friendships follow the same patterns as is predicted by mating strategies: men consider their friends more sexually attractive; they over-perceive the females' sexual interest, while women value physical protection, as well as signs of "good mate" material in their male friends.

Sexual Attraction in Opposite-Sex Friendships

Sexual attraction is often experienced in opposite-sex friendships, and it can be considered as a benefit (e.g., "friends with benefits") or as a cost, when it negatively impacts the friendship. Research has shown attraction is often experienced in opposite-sex friendships (e.g., Reeder 2000), and if communicated, it can transform a friendship into a romantic relationship, end a friendship completely, continue it as a "friendship with benefits," or, in some cases, friends find a way to keep their relationship platonic (Halatsis

and Christakis 2009). For instance, Afifi and Faulkner (2000) reported that around 50% of their participants experienced sexual intercourse in an opposite-sex friendship, some of them even when involved in romantic relationships. This points us toward the potential cost and benefit of opposite-sex friendship: the threat it poses for the relationship with a romantic partner and a possible romantic relationship which can develop from a friendship.

Advantages and Disadvantages of Having Opposite-Sex Friends

Opposite-sex friends have certain benefits compared to same-sex friends: people learn more about the opposite sex and adequate ways to communicate, which can be beneficial in attracting and keeping a partner. Additionally, in opposite-sex friendships, men experience intimacy and emotional depth that is mostly lacking in friendships between men, while women can benefit from physical protection that a male friend can provide. Considering the fact that some friendships develop into romantic relationships, opposite-sex friends can be a pool of potential mates, which have already been evaluated and are considered compatible in some way. Opposite-sex friends will not become rivals during mating, which sometimes happens in same-sex friendships.

Partner's jealousy of an opposite-sex friend can be a potential disadvantage of this type of relationship, and men and women do consider attraction toward their opposite-sex friend as a cost of that relationship. Considering the fact that stronger attraction toward an opposite-sex friend is related to lower romantic relationship satisfaction (Bleske-Rechek et al. 2012), partner's jealousy seems evolutionarily justifiable.

Methodological Considerations in Researching Opposite-Sex Friendships

Opposite-sex friendship is considered as a platonic relationship between men and women; however, the previously mentioned findings signify a

need for a careful description of “friend” when opposite-sex friends are researched. Considering the frequently present attraction and sexual contact in opposite-sex friends, it is necessary for a researcher to carefully consider the possible “types” of friendships when choosing a sample and discussing their results.

Conclusion

Opposite-sex friends are essential members of a modern way of life and provide additional assets in one’s social context. Research results confirm the “by-product hypothesis”: the frequently present attraction in this type of friendship is a manifestation of mating strategies activated in a novel environment.

Definition

Interpersonal connections with peers of the opposite sex that are based on the quantity and quality of mutual respect, appreciation, and liking.

Introduction

Research clearly demonstrates the benefits of positive peer relationships for children's development (Martin and Dowson 2009). Findings show that children who have positive relationships with peers tend to be higher in academic outcomes (e.g., Martin et al. 2009) and personal well-being (e.g., Liem and Martin 2011). Research also shows that opposite-sex and same-sex peer relationships both positively impact children's development, but often in distinct ways (Liem and Martin 2011). Evolutionary psychology helps shed light on how peer relationships function in children's lives as well as some of the distinctive ways opposite-sex and same-sex peer relationships impact development. With a focus on opposite-sex peer relationships among children and the main contexts in which they interact (e.g., school), this discussion explores relevant research and theory through an evolutionary psychology lens.

Peer Relationships

Children's peer relationships and their effects on development have been explained from a variety of psychosocial and psychobiological perspectives. Under one such perspective – evolutionary psychology – it has been established that for individuals to coexist over time, they must balance their own interests with the interests of the group to which they belong. Thus, individuals are cooperative at key points in development (Barrett et al. 2002). Children coexist as peers in a group and adaptive intragroup synergies are developed through positive peer relationships. These positive peer relationships provide support and assistance for the child and the group to which he or she belongs.

Evolutionary educational psychology is particularly relevant to child development. Evolutionary educational psychology proposes two highly influential psychological systems. Biologically primary (folk) psychological systems that have an evolutionary basis and involve processing information related to self, others, and group

dynamics (Geary 2012). Biologically secondary psychological systems are acquired through individuals' interactions with their environment. Thus, biologically primary psychological factors and processes refer to pan-human phenomena such as social interaction and communication (Geary 2012). Thus, peer relationships (including their underlying mechanisms such as cooperation) are socially based phenomena that would be considered biologically primary knowledge and skill that humans are evolutionarily motivated to acquire and apply (Geary 2012).

Notably, however, at the same time as children are motivated to cooperate and socially interact, there are many contexts (e.g., classrooms) in which they must also compete to secure resources for survival and fitness (e.g., teacher's attention and support). Drawing on early work by Hamilton (1964) suggesting that there is "direct fitness" (producing one's own offspring) and "indirect fitness" (helping others to produce offspring that share one's genes), Martin (2017) has suggested that children can achieve by their own efforts ("direct achievement fitness") or they may also help other children achieve. In so doing, they may lift the group to a higher level of aggregate achievement that can assist their own capacity to achieve ("indirect achievement fitness"). This further establishes a potential evolutionary psychology basis for positive peer relationships in childhood.

Hamilton (1964) also argued that the more members in the group are connected to each other (referred to as the "coefficient of relatedness"), the less the benefits need to be for cooperative behavior to occur. In childhood, then, it might thus be argued that the higher the quality of peer relationships, the more cooperation is likely to occur. Indeed, a body of writing on cooperative contexts attests to the positive consequences of positive peer relationships in these contexts (e.g., Johnson and Johnson 2008).

The frequency of interactions among peers is also critical. The more peers interact, the more it makes sense for them to cooperate and assist each other. Moreover, to the extent they do, their academic and personal wellbeing outcomes are enhanced (Johnson and Johnson 2008).

Particularly in childhood, there is a greater frequency of peer interactions among same-sex peers and research has identified positive outcomes through these same-sex peer relationships (Liem and Martin 2011; Martin et al. 2009). Although ever-present, opposite-sex peer relationships are relatively less salient.

Opposite-Sex Peer Relationships

Studies on the relative effects of opposite-sex and same-sex peer relationships have identified similarities and differences in terms of academic and personal wellbeing outcomes (e.g., Liem and Martin 2011). There is agreement among researchers that both same-sex and opposite-sex peer relationships share functional importance by affording avenues for children to meet their psychosocial needs, such as providing sources of self-esteem, ego support, and affirmation of competence (Liem and Martin 2011).

It is also the case that opposite-sex peers represent a source of intragroup diversity. The potential for diversity to enhance children's outcomes is suggested in "niche partitioning," a term addressing the diverse roles and expertise of group members (Sulloway 2007). In the educational context, for example, niche partitioning suggests a need to optimally utilize children's different strengths and roles to increase the "fitness" of the class. In terms of opposite-sex peer relationships, because girls and boys have distinct motivational and achievement strengths (Liem and Martin 2011), each can make unique contributions to the class and to peers of the opposite sex.

Also in classroom contexts, opposite-sex diversity may have the potential to result in less intra-group conflict and competition and better ensure that students are equipped to deal with the diverse and fluid challenges characteristic of a changing world. That is, learning environments comprising a heterogeneous mix of students may evince less intragroup conflict because there are fewer students competing for the same spoils

(or more students striving for a diversity of spoils) (Martin 2017).

Although this discussion centers on children, it is worth noting related evolutionary theorizing on opposite-sex peer relationships among adults. Although much of this theorizing inevitably is about mating and genetic survival, it also articulates some ideas arising in this discussion with regard to niche partitioning (Sulloway 2007). For example, Lewis et al. (2011) describe how during human evolution men and women faced distinct adaptive problems (e.g., pregnancy, childcare, hunting, warfare, etc.). Natural selection would favor psychological mechanisms that orient men and women to developing friendships with others who possess characteristics valuable for solving distinct problems. Because many adaptive problems are sex-linked (i.e., men and women tend to face and solve different problems), opposite-sex peer relationships will develop accordingly.

Research Findings

Following from the above evolutionary theorizing, research has shown that the positive influences of opposite-sex peers may differ from those of same-sex peers (e.g., Liem and Martin 2011). This may not be surprising as children tend to interact and develop friendships with same-sex peers in their childhood, whereas opposite-sex friendships tend to emerge more saliently in later adolescence. As noted earlier, the frequency of interaction is an evolutionary-based factor that may inform the nature and effects of peer relationships. Importantly also, the opposite-sex peers that children interact with tend to be secondary friends more than best friends (Liem and Martin 2011) and so opposite-sex peers may be less influential in children's outcomes than friends of the same sex. Thus, it has been predicted that both opposite-sex and same-sex peer relationships are influential in childhood, but the extent to which this is the case will differ. Indeed,

research has found that same-sex peers, but not opposite-sex peers, directly predict children's academic performance; both same-sex and opposite-sex peers directly predict self-esteem; and, same-sex and opposite-sex peers both significantly predict school engagement – but to a greater extent for same-sex peers. Moreover, these findings tend to be invariant across gender and age groups (Liem and Martin 2011; see Martin et al. 2009 for aligned opposite-sex findings).

Conclusion

Positive peer relationships underpin key elements of children's development. Evolutionary psychology provides insights into how peer relationships function in children's lives. This perspective also sheds light on the distinctive ways opposite-sex and same-sex peer relationships impact development. With a focus on opposite-sex peer relationships in the present discussion, evolutionary psychology provides theoretical and empirical grounds for concluding that positive interactions with peers of the opposite sex are essential for academic development and psychological well-being during childhood.

Opposition to Human Sperm Competition

Robin Baker

School of Biological Sciences, University of Manchester, Manchester, UK
C  mpeta, M  laga, Spain

Definitions

Human sperm competition: The competition, inside a woman, between sperms from two or more different men for the “prize” of fertilizing any egg the woman might produce.

Introduction

The potential evolutionary importance of sperm competition was first recognized for insects (Parker 1970), but within a little over a decade, the growing theoretical framework was being extended to a range of other animals, including humans (Smith 1984). Smith’s suggestion was seen as daring and thought-provoking, but triggered little opposition. However, when a series of papers by Baker and Bellis (see Baker and Bellis 1995) claimed evidence that sperm competition really had played a part in shaping human sexuality, resistance to the idea began to grow. Increasingly the view was expressed that even if sperm competition did occur occasionally in humans, its evolutionary significance was minimal. Some simply doubted that women behaved often enough in the way necessary for sperm competition to be a significant evolutionary force. Others reinforced their opposition with arguments based on the brevity of sperm fertility, variation in sperm biology, details of male anatomy, and most recently the genetics of ejaculates.

Female Infidelity and Levels of Extra-Pair Paternity

When first outlining the potential importance of sperm competition to human evolution, Smith

(1984) listed a range of situations in which such competition could occur: prostitution, group sex, rape, gang rape, and, on top of the list, female infidelity. Unfortunately, how often such behavior actually led to sperm competition could not be estimated. Although figures existed for all of the listed activities, not only for the USA but also for Europe, these figures could not simply be converted into rates of sperm competition nor, more importantly, how many children were conceived as a result.

When a woman conceives to a man other than her recognized partner, it is said to be a case of extra-pair paternity. Traditionally, based on a little more than hearsay and anecdotes, medical students had been taught that the level of extra-pair paternity in modern society was around 10–15%. This encouraged the belief that sperm competition led to conception often enough to be an evolutionary force.

The first direct attempt to estimate the frequency of sperm competition was made by Bellis and Baker (1990) based on a UK nationwide survey. From nearly 4000 replies, they separated out data for women being unfaithful “unprotected” by contraception during the fertile phase of their menstrual cycle and calculated that the proportion of children likely to be conceived via sperm competition was indeed likely to be of the order of 10%. On the basis of this figure, Baker and Bellis (1995), and later others, claimed that sperm competition had been common enough through human evolution to exert a significant selective pressure. Others, however, began to question this 10% figure and argue that the true value is considerably lower.

A debate over the matter springs from measures not of sperm competition but of extra-pair paternity. The earliest such investigations used blood-group analysis, the more recent DNA paternity testing, mainly in the USA and Europe. Nearly 70 studies have now been conducted, and various meta-analyses have been carried out. The most quoted figure is that obtained by Anderson (2006): only 1.7% of the assumed children of men with high paternity confidence had in reality been sired by other men.

Attempts have also been made to measure extra-pair paternity rates in the historical past using lineages stretching as far back as 700 years ago. This group of studies all involves obtaining samples of Y chromosomes from modern-day men linked by some feature that, like the Y chromosome itself, is passed from father to son through the generations. Examples are surnames, the right to participate in certain privileged land-use schemes, and discrete immigrant populations recorded through patrilineal descent. Mismatches between Y chromosome genes and, for example, surnames can indicate extra-pair paternity in the historical past. As a group, these studies generally seem to show per-generation rates of extra-pair paternity of around 1% (Larmuseau et al. 2016) and are all far lower than the 10% initially accepted by early authors.

Measures of extra-pair paternity are not in themselves measures of conception via sperm competition because, among other causes, not all cases of extra-pair paternity result from such a scenario. Nevertheless, the general impression given by so many extra-pair paternity figures of ~1% is that sperm competition may not be as important in human evolution as initially believed.

Sperm Fertility

Gomendio and Roldan (1993) were the first to question the contribution of sperm competition to human evolution that Baker and Bellis had been promoting in their papers. The formers' primary argument was that human sperm were fertile for such a short time that for sperm competition to occur a woman would have to mate with two men within only 2–3 days. Gomendio and Roldan thought it unlikely that such short-term "double-mating" happened often enough to be a selective force. Evidence that human sperm remained fertile inside a woman for longer than 2–3 days, such as the 5 days claimed by Barrett and Marshall (1969) or even longer by others, was dismissed by Gomendio and Roldan as unreliable. So too was the evidence published earlier by Bellis and Baker (1990) that short-term double-mating by

women did occur often enough to be evolutionarily significant.

Sperm Biology

Van der Horst and Maree (2014) investigated sperm biology for three animal species that they suspected evolved under very low levels of sperm competition. The species concerned were a passerine bird – the Eurasian bullfinch (*Pyrrhula pyrrhula*) – and two mammals, the greater bandicoot rat (*Bandicota indica*) and the naked mole-rat (*Heterocephalus glaber*). The authors noted that the sperm of all three of these species shared characteristics, such as low swimming speed and a high proportion of abnormal sperm, that they argued would evolve only under low levels of sperm competition. Van der Horst and Maree then compared the sperm biology of their three species with that of primates and claimed a greater similarity with the sperm of humans and gorillas, the latter evolving under low levels of sperm competition, than with the sperm biology of chimpanzees, evolving under high levels. In the authors' view, this similarity was evidence that humans evolved under low levels of sperm competition.

Male Genitalia

A variety of studies have compared the male genitalia of humans with the genitalia of other primates (see Dixson 2009). Length and diameter of the penis, presence and shape of the terminal coronal glans, presence and size of penile spines and internal penis bone, size of seminal vesicles, and size of testes (relative to body size) have all been analyzed across species. Although a range of primates are often included, the main question usually asked is whether human genitalia are more similar to those of low-sperm-competition gorillas or high-sperm-competition chimpanzees. Invariably, human genitalia emerge as intermediate between these two near relatives. Nevertheless, Dixson (2009) concluded that the weight of such evidence leans toward humans being more

similar to gorillas and hence toward sperm competition having played an insignificant part in the evolution of human sexuality.

Seminal Fluids

In recent years a number of investigations have estimated the rate of evolution of genes that encode aspects of primate ejaculates. Measured rates often correlate with the level of sperm competition in the different lineages. Not all conclusions concur, but one of the most quoted is from the study by Dorus et al. (2004). This showed that the evolution of *SEMG2*, the gene encoding a main structural component of coagulated semen, is accelerated under conditions of high sperm competition. The rate of evolution in humans, however, was much nearer to that of gorillas than chimpanzees, suggesting a low level of sperm competition in the human evolutionary past.

Conclusion

A range of evidence has been amassed that some authors claim show the human lineage evolving under low levels of sperm competition. It should be noted, however, that none of the streams of evidence are universally accepted. The measures of levels of extra-pair paternity all suffer from methodological quirks that could easily mask a population sperm competition level as high as 10% (Anderson 2006). The length of time the sperm stay fertile inside a woman and the frequency with which women double-mate during that time are also highly debatable (Baker and Bellis 1995). So are conclusions based on sperm biology (Baker and Bellis 1995) and male genitalia (Baker 1997; Gallup et al. 2006; Marczyk and Shackelford 2010), whereas those based on seminal fluids are simply contradictory (Leivers and Simmons 2014).

Essentially, interest in human sperm competition has divided authors into three main groups. The first (e.g., Baker and Bellis 1995; Gallup et al. 2006; Smith 1984) considers that

human sperm competition was very common in the past, is still moderately common today, and as such has been and still is a major selective pressure on human sexuality. The second (e.g., Birkhead 2000; Dixon 2009; Gomendio and Roldan 1993) proposes that sperm competition was minimal in the past, is trivial today, and has played either a minor or zero role in human evolution. The third (Marczyk and Shackelford 2010) maintains that, past or present, the actual level does not matter. As long as sperm competition occurs with some predictability and carries large fitness costs, even a relatively low frequency can act as a powerful selective pressure.

For the moment, the second (“low-level”) group appears to be in the ascendancy. However, the question of how important sperm competition has been in the evolution of human sexuality is still very far from settled.

Optimal Clutch Size

Jeremy Davis

University of Washington Tacoma, Tacoma, WA, USA

Synonyms

[Interbirth interval](#); [Lack clutch size](#); [Optimal litter size](#)

Definition

The number of offspring individual females are predicted to produce in a given breeding attempt (clutch) when there is a trade-off between the number of offspring in a clutch and the quality of each offspring.

Introduction

The study of life history evolution explores how species maximize fitness when traits directly linked with fitness (e.g., life span, fecundity, offspring quality and quantity) are negatively correlated with each other. One of the best-studied life history trade-offs is the relationship between offspring quantity and quality, in which additional investment in any one offspring will generally reduce the number of offspring a parent can produce. Economic models have been used to predict the clutch or litter size that will maximize evolutionary fitness. These predictions depend on shape of the relationship between offspring quality and fitness and offspring quality and quantity. In animals (and, in particular, birds), this predicted number of offspring is called the “optimal clutch size.”

Lack's Model

One of the first attempts to predict life history decisions using economic models was David

Lack's work predicting optimal clutch and litter size in birds and mammals (Lack 1947). Previous hypotheses about the determinants of clutch size posited that females would maximize fitness by producing the largest clutches possible given the species' physiological constraints. Lack hypothesized that a trade-off between clutch size and the per capita survival rate of clutch members might favor the production of smaller clutches than physiological possible. For example, while five eggs represent the potential for higher evolutionary fitness than four eggs, a per capita survival rate of 0.2 in a five-egg clutch will result in lower fitness at fledging (an estimated one surviving fledgling) than four eggs with a survival rate any higher than 0.25 (>1 surviving fledgling). Lack specifically suggested that food limitation might drive such a trade-off between clutch size and survival rate, but difficulty incubating or carrying large clutches and the potential for large clutches to attract predators are also potential sources of a trade-off between clutch size and offspring survival (Godfray et al. 1991).

Like any model in behavioral or evolutionary ecology, models of optimal clutch size serve to make testable predictions about behavior based on hypotheses about the relationship between those behaviors and evolutionary fitness. Lack's model hypothesized that the primary fitness trade-off of increased clutch size was the survival rate of fledglings within that clutch; this predicted clutch size is often referred to as the "Lack clutch size." Observational studies have revealed that clutches are typically smaller than the predicted Lack clutch size (Godfrey et al. 1991). Moreover, the experimental addition of offspring to clutches frequently demonstrates that animals can successfully produce more surviving offspring than they typically do (Van der Werf 1992). This suggests that either (1) estimates of the survival cost of increased clutch size are underestimated and/or (2) additional costs of increased clutch size need to be taken into account.

Individual Variation and the Underestimation of Fitness Trade-Offs

Observational studies used to assess the trade-off between clutch size and offspring survival are complicated by individual-level variation in the ability to successfully produce and rear clutches. The largest clutches in a population may be produced by females in particularly good condition or with access to particularly rich resources. These same females may also be better able to ensure the survival of offspring than low-quality females with smaller clutches. Such individual variation can mask the trade-off between clutch size and survival that likely occurs among individuals within a particular quality class. Therefore, in populations with interindividual variation, the cost of increased clutch size can be underestimated and the optimal clutch size thus overestimated (Fig. 1; Pettifor et al. 1988).

Additional Costs of Clutch Size

While Lack focused on the cost experienced by offspring within a given breeding season, increased clutch size may have fitness costs experienced in future breeding seasons by clutch members or their parents. The "cost-of-reproduction" hypothesis posits that large clutch sizes reduce the condition and survival of parents, thus reducing the production of future clutches. Moreover, large clutch size may influence the future reproductive capacity of clutch members. Both of these costs are reflected in the optimal clutch size of wrens: females whose clutches were experimentally increased produced smaller hatchlings during the experimental year, and themselves experience lower hatchling survival during the following year (Hodges et al. 2015).

Some hypotheses posit that females produce smaller clutches as a bet-hedging strategy against large costs that are only occasionally experienced. For example, the "bad years" hypothesis (Boyce and Perrins 1987) predicts that females maximize their geometric mean fitness by avoiding the

Optimal Clutch Size, Fig. 1 The influence of individual variation on estimates of the clutch size – survival trade-off. In all three plots, the actual relationship between clutch size (or interbirth interval [IBI]) and offspring survival is the same (*solid lines*). Where there is individual variation, females in better condition (*thick lines/dark circles*) can produce larger clutches (or shorter IBIs) and achieve higher

offspring survival than females in poor condition (*thin lines/light circles*). If females in better condition produce large clutches, estimates of the trade-off between clutch size and survival (*dotted line*, based on three hypothetical individuals) become increasingly inaccurate as individual variation in condition increases

production of large clutches that, while successful in times of plenty, lead to a catastrophic loss of fitness in “bad years,” when resources are scarce. The “parasitism insurance hypothesis” – another bet-hedging hypothesis – argues that birds may produce smaller clutches in order to accommodate the occasional additional offspring introduced via intra- or interspecific clutch parasitism. Bet hedging may also explain why some birds produce clutches of two eggs when only one offspring survives. While energy invested in the second egg typically represents wasted effort, the second egg insures against a total loss of fitness if the first egg is infertile or otherwise nonviable (Godfray et al. 1991).

Individual Optimization

The recognition that individuals can vary in their ability to successfully rear clutches led to the development of the “individual optimization hypothesis,” in which intrapopulation variation in clutch size is explained by each individual producing a clutch size that optimizes fitness given that individual’s particular “state” or “condition.” This hypothesis predicts a positive correlation between clutch size and some measure of

condition (e.g., size) and that removing or adding offspring to the females preferred clutch size will reduce her fitness. Both of these predictions have been met in studies on great tits (Pettifor et al. 1988) and Richardson’s ground squirrels (Risch et al. 2007) and thus potentially explain the extreme clutch size variation seen in these species.

Litter Size and Interbirth Interval in Humans

In humans, the optimal litter size is likely to be one. It is difficult for women to meet the nutritional requirements to support nursing more than one infant, and studies on hunter-gatherers indicate that women are typically unable to carry more than one infant (Hill and Kaplan 1999). Life history data collected in two Norwegian parishes from 1700 to 1900 indicates that the evolutionary fitness – measured as total grand offspring – of the mothers of twins was less than or equal to that of the mothers of singletons and the mothers of offspring made singleton via the death of their twin (Skjærvø et al. 2009).

A related life history trade-off more relevant to human variation is interbirth interval. Shorter interbirth intervals produce more infants but may

increase per offspring mortality rate. Research on the !Kung (Blurton-Jones 1987) and the Ache (Hill and Kaplan 1999) both revealed a negative relationship between interbirth interval and offspring mortality, supporting the expected trade-off between offspring quantity and quality. However, in the Ache, this mortality cost was not large enough to explain the length of IBI in this population (it was predicted to be shorter). As with animal studies, estimates of optimal IBI in these instances may underestimate optimal IBI because they do not take into account additional costs of reproduction or underestimate those costs by ignoring individual variation (Fig. 1). For example, a recent study on preindustrial Finns has demonstrated a negative genetic correlation between mean IBI and parent life span (Pettay et al. 2005), suggesting that increased mortality in parents is an additional cost of shorter IBIs.

Conclusion

Overall, clutch and litter sizes in vertebrates are smaller than individuals are physiologically capable of producing. This underproduction of offspring is most likely driven by a trade-off between offspring quantity and quality. In general, models that hypothesize that the cost of larger clutch size is only paid by clutch members and only experienced within a particular breeding season tend to overestimate optimal clutch size. Models that also include costs to parents, irregular but large costs, and individual variation tend to better predict the clutch sizes seen in nature.

Optimal Designs

Holly Elmore

Harvard University, Cambridge, MA, USA

Products and Byproducts of Natural Selection

What is the proper way to interpret the appearance of design in nature? Before 1859 and the publication of Darwin's *On the Origin of Species*, the answer seemed obvious – design means a designer. In *Natural Theology*, theologian

William Paley famously analogized the appearance of design in the living world to the appearance of design in a man-made object, a watch:

... [S]uppose I had found a watch upon the ground, and it should be inquired how the watch happened to be in that place ... There must have existed, at some time, and at some place or other, an artificer or artificers, who formed [the watch] for the purpose which we find it actually to answer; who comprehended its construction, and designed its use. ... Every indication of contrivance, every manifestation of design, which existed in the watch, exists in the works of nature; with the difference, on the side of nature, of being greater or more, and that in a degree which exceeds all computation. (Paley 1809)

In his book *The Blind Watchmaker* (Dawkins 1986), Richard Dawkins answers Paley's supposition:

The analogy ... between watch and living organism is false. All appearances to the contrary, the only watchmaker in nature is the blind forces of physics, albeit deployed in a very special way. A true watchmaker has foresight: he designs cogs and springs, and plans their interconnections, with future purpose in his mind's eye. Natural selection, the blind, unconscious, automatic process which Darwin discovered, and which we now know is the explanation for existence and apparently purposeful form of all life, has no purpose in mind. [...] If it can be said to play the role of watchmaker in nature, it is the *blind* watchmaker.

Paley's observation is still true today: we instinctively recognize purpose and intention in living things the same way that we recognize design in manmade artifacts. We now know that living things evolved into their present forms, and we look at how well organisms "fit" within the challenges of their environments in order to determine what selective pressures shaped them. But how well should we expect organisms to meet those challenges? What level of craftsmanship does the blind watchmaker employ? What does it mean when we see less than optimal designs in nature?

Case Study: The Spandrels of San Marco

We may have explained away the need for Paley's intelligent watchmaker, but the question remains, how good of a watchmaker is our blind watchmaker, natural selection? Are living things

particularly well designed? And does *everything* have to be the product of natural selection? Some living things have features that seem poorly adapted to their environments. It's also possible that some features that look like great designs to human minds might only appear that way in hindsight or through the lens of overly felicitous post-hoc reasoning. How many features are mere "spandrels" – byproducts of genuine adaptations? In their oft-touted 1979 paper, *The Spandrels of San Marco and the Panglossian Paradigm: A Critique of the Adaptationist Programme*, Stephen Jay Gould and Richard Lewontin compare the design of living things to that of the Cathedral of San Marco in Venice, which features beautiful mosaic portraits of the evangelists in its spandrels – the spaces between the cathedral's dome and the curved arches that support it:

The design is so elaborate, harmonious, and purposeful that we are tempted to view it as the starting point of any analysis, as the cause in some sense of the surrounding architecture. But this would invert the proper path of analysis. The system begins with an architectural constraint: the necessary four spandrels and their tapering triangular form. They provide a space in which the mosaicists worked; they set the quadripartite symmetry of the dome above.

... [E]volutionary biologists, in their tendency to focus exclusively on immediate adaptation to local conditions, do tend to ignore architectural constraints and perform just such an inversion of explanation. (Gould and Lewontin 1994)

The metaphorical spandrel here is what Gould would later term an exaptation – "a character, previously shaped by natural selection for a particular function (an adaptation), [coopted] for a new use" (Gould and Vrba 1982). This framing of exaptation can be misleading, as there are no raw evolutionary materials – every feature that is genuinely adapted for a given purpose must have begun as part of a different feature – but it is useful to consider whether the selection pressures an organism faces in a modern environment are the same as those that contributed the most to its design. "Spandrel" is still used interchangeably with "byproduct" in evolutionary biology and psychology, and the phrase "just a spandrel" has something of a pejorative connotation.

The concept of architectural constraints adds explanatory power to our story of the spandrels of San Marco. The spandrels do not exist simply to display mosaics of the evangelists, but, contra Gould and Lewontin, neither are the mosaics an afterthought entirely secondary to the architecture of the church. In *Darwin's Dangerous Idea* (1996), Dan Dennett shows that our understanding of the spandrel could benefit from an adaptationist analysis. He begins by pointing out that San Marco features only one kind of spandrel, more properly known as a “pendentive”:

Not only were the pendentives just one among many *imaginable* options; they were just one among the readily *available* options. Squinches had been a well-known solution to the problem of a dome over arches in Byzantine architecture since about the seventh century.

What the actual design of the San Marco spandrels—that is, pendentives—has going for it are mainly two things. First, it is (approximately) the “minimal-energy” surface (what you would get if you stretched a soap film in a wire model of the corner), and hence it is close to the minimal surface area (and hence might well be viewed as the optimal solution if, say, the number of costly mosaic tiles was to be minimized!). Second, this smooth surface is ideal for the mounting of mosaic images—and that is why the Basilica of San Marco was built: to provide a showcase for mosaic images.

The conclusion is inescapable: the spandrels of San Marco aren't spandrels even in Gould's extended sense. They are adaptations, chosen from a set of equipossible alternatives for largely aesthetic reasons. They were designed to have the shape they have precisely in order to provide suitable surfaces for the display of Christian iconography. (Dennett 1996)

Dennett advocates the intentional stance when approaching biological and, by extension, psychological phenomena, assuming that complex features are adaptations that evolved to serve a purpose. Though Gould and Lewontin rightly point out natural selection is not the direct cause of all characteristics, it *is* the only cause of complex adaptations. Even though the spandrels of San Marco are in some sense byproducts, they can also be viewed on their own terms as adaptations when compared to equally possible alternatives. It was by assuming the intentional stance that Dennett was able to find a possible adaptive purpose to the spandrels.

The debate over the appropriate perspective on possible adaptations may seem to come from the armchair – why should we care whether adaptation is more or less pervasive in shaping living beings than the genetic drift, developmental constraints, and genetic inertia that also play a role? Can't we just look at the evidence for any given case?

One reason that we must consider grand questions of causation is that the balance of the various evolutionary forces informs our null expectations. Any attempt to reverse engineer relies on the reasoning that complex, well-adapted features don't arise by chance alone, so the degree of their aptness for a given purpose is evidence that they evolved for that purpose.

More fundamentally, the intentional stance is often the only place to start when asking “why” questions about design in living beings. “Adaptationism” is a productive approach for generating hypotheses and making novel, testable predictions (Barkow et al. 1992). While any particular explanation of adaptive purpose is just a hypothesis until it is validated, it is important to have the intellectual warrant to proceed from the assumption that complexity has an adaptive explanation. In fact, the same instinctive recognition of design that led Paley to believe in an Intelligent Watchmaker sets today's evolutionary scientists on the course to investigating adaptations.

What Is Optimal?

A Note on Terminology

In common parlance, “optimal” is used interchangeably with “maximal,” but for our purposes, it is useful to distinguish the two. In engineering, optimal means “satisfactory, the best solution given all the constraints,” while maximal means “greatest possible,” and these are the definitions that I will adopt here. It is important to note that these terms are not always distinguished in biology or psychology, and their definitions may even be reversed.

There is a deeper philosophical issue that causes confusion between optimal and maximal

designs – actualism vs. possibilism. The *Stanford Encyclopedia of Philosophy* explains:

Actualism is the philosophical position that everything there is – everything that can in any sense be said to be – *exists*, or is *actual*. Put another way, actualism denies that there is any kind of being beyond actual existence; to be is to exist, and to exist is to be actual. Actualism therefore stands in stark contrast to possibilism, which [...] takes the things there are to include possible but non-actual objects. (Menzel 2016)

The disagreement boils down to what benchmark we are using to evaluate natural selection's designs. In our terms, adaptationists like Dawkins tend to be actualists – focused on how well natural selection solves a problem within its constraints and dismissing other possible sets of constraints as beside the point because those were not the constraints that *actually* impinged on natural selection in the given case. Those like Gould and Lewontin that focus on contingency and point out the inadequacy of nature's solutions often appeal to different possible, but not actual, circumstances under which the trait could have evolved to be better at solving the problems it now faces. Possibilists tend to see actual reality as just a subset of what could have been, whereas actualists tend to view what actually exists as all that could have been. I cannot resolve the actualism vs. possibilism debate in this chapter, but mention it in the hopes of empowering the reader to recognize sources of disagreement and misunderstanding around the concept of optimal designs.

I will henceforth use the word “optimal” to mean “best in the actualist sense” and “maximal” to mean “best in the possibilist sense.” The concept of the adaptive landscape illustrates how a solution can be optimal, a local peak on the landscape, but not maximal, a global peak with respect to fitness. [Define fitness?]

Optimal Designs Are Peaks on the Adaptive Landscape

Darwinism is not a theory of random chance. It is a theory of random mutation plus non-random cumulative natural selection. ... Natural selection ... is a non-random force, pushing towards improvement. ... Every generation has

its Darwinian failures but every individual is descended only from previous generations' successful minorities. ... [T]here can be no going downhill - species can't get worse as a prelude to getting better. – Richard Dawkins, *Climbing Mount Improbable*

Adaptive landscapes (also known as “fitness landscapes”) map genotype or phenotype to reproductive fitness. For any genotype or phenotype, all possible versions can be plotted as points on an adaptive landscape to show how fit each possible version of the phenotype or genotype is. Sewall Wright (1932) described an adaptive landscape as a n -dimensional space where “the entire field of possible gene combinations be graded with respect to adaptive value under a particular set of conditions.” For simplicity's sake, they are often rendered in two dimensions and only with respect to one genotype or phenotype as below:

IMAGE adapted from: Public Domain, <https://commons.wikimedia.org/w/index.php?curid=193687>

Here we can clearly see how selection works given its constraints. Natural selection is a hill-climbing algorithm – it can only push a population up toward the nearest peak on the adaptive landscape. Theoretically, adaptive landscapes reflect all the constraints that shape them – the abiotic and biotic environment as well as the organism's other features. The constraints on a feature may be static or shift over time. When the constraints shift, the adaptive landscape reflects that shift, because the map of phenotype or genotype to fitness has changed. Even though it would be impossible to map every constraint, the metaphor of an adaptive landscape is useful because it shows us why only some paths are available for natural selection to climb. Natural selection

cannot tell which peak is highest (maximal); it can only tell which direction is up.

A change in the shape of the landscape does not change natural selection itself, but it can channel the action of natural selection into a new direction by introducing new selection *pressures*. In adaptive landscape terminology, a selection pressure is the incline of the peak. The stronger the selection pressure, the steeper the incline. There is a great deal of room for chance and contingency in traversing an adaptive landscape, particularly in what genetic variation becomes available (i.e., which spots individuals could occupy on the landscape), but chance of this kind is not chance in the action of natural selection. Natural selection is always an optimization algorithm that accumulates chance events, such as beneficial mutations, in a nonrandom way.

Individuals in a population occupy one point on the landscape at any given time, and the population evolves when its position on the landscape changes. Occupying a peak on the fitness landscape means the population has attained a local maximum in fitness, or an optimal design.

Natural Selection Cannot Cross a Fitness Valley

Natural selection increases the proportion of alleles in the population that lead to greater reproductive success. This principle is axiomatic. Therefore, natural selection cannot push a population to cross a valley in the fitness landscape. Populations can get stuck on a local maximum and rendered unable to access higher peaks, because doing so would require passing through generations in which individuals of lower fitness had higher reproductive success than those of higher fitness – which natural selection will not do by definition.

Just because natural selection cannot push a population across a valley doesn't mean it is impossible for populations to move from peak to peak. There are other evolutionary forces, particularly genetic drift, that can move a population across the landscape regardless of the fitness consequences. Wright (1932) referred to this

phenomenon as “shifting balance.” In effect, drift allows a population to sample a larger area of the fitness landscape. Usually, this simply means lower mean fitness in that population, but sometimes a subset of individuals strays far enough away from one peak to “shift the balance” so that natural selection begins to drive it up another peak.

Genetic Drift Gets in the Way of Natural Selection

When genetic drift is strong enough to overcome selection, you get stuck with features that were not chosen for any particular reason but also are within a range of acceptable harm or sub-optimality. Because genetic drift is essentially sampling error, the balance of selection and drift depends on the size of the population. In small populations, drift can be more influential relative to selection because the sampling of alleles with each new generation is less representative of the previous generation than it would be in a larger population. Response to selection is measured in generations, so the longer generation times of large animals like humans put a speed limit on natural selection while also increasing the role of genetic drift. This means that evolution happens very slowly for humans unless a selection pressure is very strong.

Natural selection is the only process that can lead to complex adaptations. Drift can sometimes lead to better designs, but only by accident. Drift cannot preferentially discover high ground on the adaptive landscape the way natural selection can. And since there are many more ways to fail to solve a problem than to solve it, drift is usually a drag on fitness.

What “Optimal” Means

In adaptive landscape terminology, optimal means a local peak. A local peak may also happen to be a global peak, or maximum. When speaking of natural selection, an optimal design can only mean one that achieves a local maximum on the fitness landscape with regard to selection pressures felt probabilistically throughout a lineage's past. There are no absolutely optimal designs.

A design can only be “optimal” with respect to its constraints. If there were no constraints on a design, there would be nothing to judge it by.

What “Optimal” Does Not Mean

Optimal designs are the best available, not the best possible. (Even designs that appear to occupy global maxima could still be made better if not for the physical constraints of our universe.) Nor does optimal mean inevitable or predetermined. How well a design feature performs a given task depends on the solutions available in design space, the genetic variation available to select on, and response to selection, which is not always strong or fast.

Also note that optimal designs may not be recognizably elegant – sometimes a “kluge,” a clumsy but effective design (Marcus 2008), is the optimal solution to a problem given the energy budget or developmental constraints.

Optimal for What Purpose? And for Whom?

The mind is what the brain does. – Marvin Minsky

The whole purpose of our search for a ‘unit of selection’ is to discover a suitable actor to play the leading role in our metaphors of purpose. – Richard Dawkins, *The Extended Phenotype*

The topic of optimal designs is contentious and confused enough when we’re talking about architecture and spandrels. It’s even more confusing to talk about the design of the mind because the mind doesn’t just follow whatever implicit goal natural selection moves it toward. The mind adopts its own goals. Failure to distinguish natural selection’s “goals” from the mind’s volition can make discussing the evolution of the mind nearly impossible.

The brain is the hardware from which the mind arises. Like a computer, the hardware was designed so that the machine could be applied to certain general purpose computations (Pinker 1997). Unlike a computer, the brain evolved by natural selection. When we use our on-board computer, we can adopt instrumental, shorter term

goals than natural selection. Mind and brain evolved so that we could adopt those short term goals, but natural selection cannot dictate what those instrumental goals should be. Is a mind optimal if it follows natural selection’s “goal,” or is it optimal if it does what it, the mind, wants?

Richard Dawkins refers to goals and purposes adopted by minds as “neo-purposes” to distinguish them from the “archeo-purpose” of natural selection (ref: https://www.youtube.com/watch?time_continue=1776&v=mT4EWCrfdUg).

Brains have evolved with various capacities that assist the survival of the genes that made them. Among these evolved capacities is the ability to set up goals, or purposes. [...] The brain is a kind of on-board computer used to control the body’s behavior in ways that are beneficial to the genes that built it. It can perceive the outside world. It remembers things. It learns the consequences of its actions—good and bad. It sets up simulated models in imagination [...] It sets up purposes or goals in the sense of neo-purpose. The capacity to have a mental goal, or neo-purpose, is an adaption with a survival value, or archeo-purpose.

The mind can easily adopt neo-purposes that are at odds with the archeo-purpose of the genes and the blind processes that created it, particularly as it finds itself in environments the genes haven’t “seen” yet through natural selection. Using contraception, for example, allows our brains to satisfy the desire for sex without ever producing the children sexual urges evolved to promote. The misgivings about children that lead us to use contraception have a long history as well – but the recent advent of highly effective birth control methods has changed the adaptive landscape by changing the consequences of these drives (Dawkins 2009). Philosopher Alan Gibbard (1990) points out that the implicit goals of the genes shouldn’t dictate our goals as their vehicles:

It is crucial to distinguish human goals from the Darwinian surrogate of purpose in the “design” of human beings [...] The Darwinian evolutionary surrogate for divine purpose is now seen to be the reproduction of one’s genes. That is not, as far as I know, been anyone’s goal, but the biological world looks as if someone quite resourceful had designed each living thing for that purpose [...] A like conclusion would hold if I knew that I was

created by a deity for some purpose of his: his goal need not be mine.

Our brains are much more optimal for an environment that has disappeared, one in which the desire for sex was enough to ensure the creation of offspring. John Tooby and Leda Cosmides argue that the most productive approach to evolutionary psychology considers the ancestral environment of modern humans, particularly the Paleolithic era during which anatomically modern humans evolved (Barkow et al. 1992). So what is being optimized when there are multiple competing interests at stake?

Game Theory and Evolutionary Stable Strategies

When multiple agents are in conflict, it no longer makes sense to speak of optimal designs because there is no one goal with respect to which the design *can* be optimal. What we get are Nash equilibria or evolutionarily stable strategies (ESS), strategies which are unbeatable by any newly introduced strategy (Maynard Smith 1972). Essentially, a stable design is reached when there is a stalemate among all the conflicting goals. These situations are the province of game theory.

Symbiosis and Parasitism

The same human individual can host a number of different organisms with different goals. Human gut microbes may have a range of psychological effects, including the ability to affect mood (De Palma et al. 2014). Humans may also host parasites that increase their own fitness by manipulating our bodies, such as when the influenza virus causes us to sneeze and spread viral particles. Parasites can also influence their own fitness by manipulating a host's mind, such as when *Toxoplasma gondii* makes mice more aggressive and willing to confront cats, who are the parasite's desired next host. *Toxoplasma gondii* cannot successfully complete its life cycle in humans, but infection with *T. gondii* can nonetheless affect human behavior (Flegr 2007). Here, a parasite employing very well designed host manipulation causes very suboptimal behavior for both intended and unintended hosts.

Intragenomic Conflict

Human genes can only successfully reproduce by making new humans, but that does not mean that all the genes in the human genome share the same goals. The genes within the genome have largely overlapping goals, but the fiercest battles are often fought over scraps. For instance, alleles that are marked as either coming from the mother or the father (imprinted) promote behavior in offspring that benefits that parent-of-origin's reproductive success (Moore and Haig 1991). Where mom and dad's genes disagree, there are evolutionary games.

The brain appears to be a major arena of conflict, judging by the fact that imprinted genes are disproportionately expressed in the brain compared to other tissues (Davies et al. 2005). The contested resource in this case may be how much support offspring can draw from relatives that are asymmetrically related to them at the causal locus. For example, babies with the imprinting disorder Angelmann's syndrome have only the father's imprinting. Angelmann's babies only sleep an hour or two a day and they want a lot of milk. This is very exhausting for the mother, who wants time to rest and recover. In the inverse disorder, Prader-Willi syndrome, which results from having only the mother's imprinting, babies sleep far more than usual and don't often want to breastfeed. There may be no one optimal amount of sleep for the baby – the amount of sleep we need may simply be a compromise between conflicting goals of the mother's genes and the father's genes (Haig 2014).

Examples of Optimal Designs and Suboptimal Equilibria in Psychology

The Regions of the Brain: Layers of a Kluge

Evolution often proceeds by piling new systems on top of old ones. The neuroscientist John Allman has captured this idea nicely with an analogy to a power plant he once visited, where at least three layers of technology were in simultaneous use, stacked on top of one another. The recent computer technology operated not directly, but rather by controlling

vacuum tubes (perhaps from the 1940s), which in turn controlled still older pneumatic mechanisms that relied on pressurized gases. If the power plant's engineers could afford the luxury of taking the whole system offline, they would no doubt prefer to start over, getting rid of the older systems altogether. But the continuous need for power precludes such an ambitious redesign. (Marcus 2008)

As Gary Marcus explains in his book *Kluge: the Haphazard Construction of the Human Mind*, a kluge is “a clumsy or inelegant – yet surprisingly effective – solution to a problem.” Marcus compares the construction of the human brain to the power plant control systems described above. The hindbrain is the most ancient part of the brain, shared by all mammals and reptiles, and controls our most basic reflexive functions such as breathing and alertness. The midbrain is involved in visual and auditory reflexes, and the forebrain is responsible for cognition, language, and judgment. Not only are higher functions like language dependent on more basic functions like breathing, higher regions of the brain are inextricably linked to the midbrain and the hindbrain (Bear et al. 2007).

The forebrain sits on top of the midbrain which sits on top of the hindbrain. The structures are arranged in descending order of evolutionary age. https://upload.wikimedia.org/wikipedia/commons/thumb/8/83/Diagram_showing_the_brain_stem_which_includes_the_medulla_oblongata%2C_the_pons_and_the_midbrain_%282%29_CRUK_294.svg/572px-Diagram_showing_the_brain_stem_which_includes_the_medulla_oblongata%2C_the_pons_and_the_midbrain_%282%29_CRUK_294.svg.png

[svg/572px-Diagram_showing_the_brain_stem_which_includes_the_medulla_oblongata%2C_the_pons_and_the_midbrain_%282%29_CRUK_294.svg.png](https://upload.wikimedia.org/wikipedia/commons/thumb/8/83/Diagram_showing_the_brain_stem_which_includes_the_medulla_oblongata%2C_the_pons_and_the_midbrain_%282%29_CRUK_294.svg/572px-Diagram_showing_the_brain_stem_which_includes_the_medulla_oblongata%2C_the_pons_and_the_midbrain_%282%29_CRUK_294.svg.png)

We have no reason to believe our brains are at a global maximum on the adaptive landscape. Ascending layers of updated systems in our brains indicate a history of updates on top of updates while the machine was still running. Evolution was constrained, in this case, by the existing brain's crucial job in survival and reproduction.

Optical Illusions: The Pitfalls of Solving an Impossible Problem

In *How the Mind Works* (Pinker 1997), Steven Pinker explains that from the perspective of light entering our eyes, there are no objects. There is just light of differing wavelengths. The mind processes that information to define objects, “the movable hunks of matter that we count, classify, and label with nouns” in our field of view. But defining objects is a difficult philosophical problem. Where does the nose end and the face begin? When does the head give way to the neck? Many objects lack clear boundaries, but the brain tries to find them all the same. The famous vase-face illusion shows that our brain can flip between entertaining one object (the vase interpretation) to another (the face interpretation) with the same visual information.

The face-vase illusion. <https://commons.wikimedia.org/wiki/File:Rubin2.jpg>

Optical illusions reveal the biases in our sensory processing. When our minds detect an object, that interpretation pops out and excludes others. In the case of the above vase-face illusion, the vase pops out and suddenly the faces are gone until the faces pop out and suddenly the vase is gone. As this illusion demonstrates, determining what it is we are seeing based on light alone is sometimes a hopelessly ambiguous problem, but the fact that optical illusions are reserved as parlor tricks shows a very robust and perhaps optimal mental design for perceiving objects.

Cognitive Biases: Optimized Shortcuts

Human cognition is subject to a long list of biases (https://en.wikipedia.org/wiki/List_of_cognitive_biases). These biases seem like suboptimal thinking because they don't always tell us the truth and occasionally fail to give accurate information. But when we view the purpose of human cognition more holistically, we see that time and processing power are limited, so in many cases shortcuts are the only way to get to an answer at all. Sometimes heuristics are better performers than slow and cumbersome solutions to those problems that aren't important to solve perfectly (Kahneman 2011).

To give a classic example, when the risks of ignoring a predator in the bushes are far greater than the risks of incorrectly interpreting the sound of a breeze as a predator in the bushes, overinterpreting noises can be an optimal solution. When our ancestors heard a sound, their minds jumped to the most emotionally salient possibility: a predator. This is called the availability heuristic – we judge the likelihood of an event by how easily it comes to mind, and emotionally salient things come to mind more easily. This is bad for accuracy, but very good for survival. A few minutes of panic and wasted time are much less costly than failing to avoid a real attack. With more time and resources, our predator detection could be even sharper, but when a heuristic works well enough, spending more resources on improving it would be gilding the lily. Those resources

could be better spent elsewhere if the cost of overreacting is small.

Summary

There is an on-going debate in evolutionary sciences about whether natural selection consistently provides optimal designs. The very idea of optimal designs hits a fault-line in biology and psychology between actualists and possibilists. The definition of optimal itself is disputed and a matter of perspective.

Natural selection can only climb hills on an adaptive landscape, and that landscape represents all the constraints on a feature's design. Genetic drift usually causes features to be suboptimal by overcoming the work of selection, but occasionally opens up the path for natural selection to climb a higher peak.

Optimal means the best design available, not the best design period. There are no absolutely optimal designs – they could always be better if some feature of the environment were better. You could almost say that the most perfect design is nothing, because then there's no problem!

Sometimes designs are not optimal with respect to their function because they are satisfying different and conflicting goals. Sometimes, as with freestanding arches and vision, conflict at one level is itself an optimal design at a higher level of function. Sometimes, as in the case of cognitive biases, a design is optimal even though it sometimes fails to perform its job because it's better to err in the right direction. Sometimes a design is suboptimal because other agents are working to exploit design weaknesses, as in the case of sensory bias.

Finally, it's important to remember that no matter how perfect or imperfect a feature appears to be, it always helps to consider what purpose it might have evolved to serve. What Stephen Jay Gould would call adaptationist thinking is a highly effective source of hypotheses, and sometimes hypotheses become part of evolutionary theory.

Oral Sex and Human Sexual Behavior

Yael Sela and Michael N. Pham
Department of Psychology, Oakland University,
Rochester, MI, USA

Definition

Sexual activity in which an individual uses their mouth to stimulate the genitals of a partner.

Introduction

Oral sex has been a prominent feature over human evolution. Oral sex occurs in many cultures, including preindustrial cultures, indicating that cunnilingus is not a culture-specific practice. Oral sex is depicted frequently in pornography, and the content of pornography is designed to appeal to evolved mechanisms (see ▶ [“Pornography as a Human Product and Source of Data”](#)). Oral sex is depicted in ancestral cave paintings. In fact, oral sex also occurs across many mammalian species, including dogs, hamsters, bovine, ring-tailed lemurs, pygmy marmosets, and Indian flying foxes. Thus, evidence suggests an evolutionary history of oral sex not only in humans but also in other mammals. Although we cannot directly

observe the human ancestral ecologies in which oral sex was adaptive, modern environments provide a useful starting point for investigation.

Oral sex is a common sexual activity in modern environments, and people report various reasons for practicing it. Men are equally likely to report their female partner performing oral sex on them (i.e., *fellatio*) and performing oral sex on their female partner (i.e., *cunnilingus*) at their most recent sexual encounter as women are to report performing fellatio and receiving cunnilingus. Most men and women report experiencing oral sex at least once in their life, and both desire to experience oral sex. Some reasons people report for engaging in oral sex include retaining virginity (because oral sex is sometimes not perceived as “real” sex; see ► [“Oral Sex and Sexual Debut”](#)), to increase their sexual reputation, to sexually satisfy their partner, to increase their own arousal, and to avoid the risk of pregnancy and diseases associated with penile-vaginal sex. However, the reasons people consciously report for a behavior, such as oral sex, may differ from that behavior’s evolutionary function.

Functional Hypotheses of Oral Sex in Humans

Several nonmutually exclusive hypotheses for the function of oral sex have been proposed, including: (1) mate retention, (2) infidelity-detection, (3) sperm-competition tactic of ejaculate adjustment, (4) fertility detection, and (5) paternal investment detection. First, oral sex may be performed as part of a benefit-provisioning mate retention strategy by both men and women (see ► [“Oral Sex as Mate Retention”](#)), because oral sex is most commonly performed within long-term relationships, is positively associated with relationship satisfaction, and women who receive cunnilingus are more likely to experience copulatory orgasm which increases their relationship satisfaction. Indeed, men and women’s performance of oral sex is positively associated with the frequency with which they provision their partner with benefits (Pham & Shackelford, 2013a; Sela et al. 2015).

Second, oral sex may function to detect infidelity because smelling and tasting a partner’s genitals may provide information about the presence of a sexual rival’s fluids in that area. Indeed, men at greater risk of a partner’s infidelity report greater interest in, and spend more time, performing cunnilingus on their partner (Pham & Shackelford, 2013b). In contrast, men do not typically perform cunnilingus on a woman during a casual, sexual encounter (i.e., “a one-night stand”), a mating context that presents no risk of a long-term partner’s infidelity. However, the infidelity-detection hypothesis has not been supported for fellatio (Pham, Shackelford, & Sela, 2013). Potential explanations for this sex-difference include asymmetries in the risk of contracting sexually transmitted diseases from fellatio versus cunnilingus and that more of rival male’s fluids are likely to linger on female genitals than female rival’s fluids are to linger on male genitals, influencing the effectiveness of, and motivation to use, oral sex as a means to detect infidelity.

Third, oral sex may function to increase men’s sexual arousal and consequent behaviors designed to increase the likelihood of fertilizing ova. Because men typically perform cunnilingus before they copulate and ejaculate, cunnilingus could influence sexual arousal and consequent sperm competition tactics such as copulatory thrusting and ejaculate adjustment (see ► [“Sperm Competition”](#) and ► [“Sperm Competition Tactics”](#)). Male sexual arousal is positively associated with ejaculate quality and volume. For example, men who report greater sexual arousal report more intense orgasm and more forceful ejaculation (Pham, Shackelford, Welling, Ehrke, Sela, & Goetz). Men experience greater arousal when the reproductive benefits outweigh the non-trivial costs of producing a higher quality, larger volume ejaculate. Men are sensitive to behavioral, visual, auditory, and olfactory cues to female fertility (Haselton and Gildersleeve 2011). Indeed, men who report spending more time performing cunnilingus report greater sexual arousal (Pham, Shackelford, Welling, et al. 2013), and time spent performing cunnilingus positively predicts ejaculate volume (Pham et al. 2016).

Fourth, oral sex (specifically, cunnilingus) may function as a sperm competition tactic to detect women's reproductive health and fertility status. Indirect evidence supporting this idea includes men's preference for smelling vaginal fluids produced during high (vs. low) fertility and men's surge of testosterone and greater copulatory interest after smelling such fluids (see also ► [“Female Orgasm and In-Pair Copulation”](#)). Additionally, common vaginal health problems (e.g., yeast infection) cause unpleasant odors which men could detect. Although both men and women desire to experience oral sex, men report a stronger, more frequent, desire for oral sex than women. This sex-difference is highlighted by the market demand for women's used underwear by men. In contrast, a much lesser demand exists for men's used underwear by women. Many male customers request that women wear underwear for a few days, and even masturbate while wearing them, to increase the amount of female fluids in the underwear before shipping them to the customer in a plastic bag to retain the genital scents. Furthermore, these customers prefer underwear worn by women who are young and attractive (i.e., fertile women). Potentially, men's desire to perform cunnilingus may be related to experiencing sexual arousal as a function of the information they gather about the woman's fertility. This hypothesized function of cunnilingus would be similar to its function in other species in which mucous from female genitals contain pheromones that elicit mounting behaviors in males.

Fifth, oral sex (specifically, fellatio) may function to assess paternal investment. Ancestral and modern mothers benefit from paternal commitment and investment (e.g., long-term resource provisioning, protection, and care for the mother and child by the father), and seem to adaptively respond to the absence of a committed partner, e.g., women are most likely to kill their newborn when they are unpartnered and lack resources – thus, avoiding the costs of raising a child under unfavorable conditions (see ► [“Filicide”](#)). It would have been potentially adaptive for women to spontaneously abort a pregnancy even earlier if they detected the absence of a committed

romantic partner. One way to assess the presence of a committed partner could be frequent exposure to his semen. Oral exposure to semen, compared to vaginal exposure to semen, is less risky (e.g., oral exposure will not lead to a second pregnancy which may jeopardize the first), and there is evidence that women who perform fellatio on their partner – especially those who ingest his semen – experience lower rates of preeclampsia (a leading cause of prenatal infant mortality) (e.g., Koelman et al. 2000).

Limitations and Future Directions

There are limitations of the few studies directly testing some of the functional hypotheses for oral sex. First, some studies relied on self-reports about oral sex and other behaviors. People may underreport the frequency with which they perform socially undesirable behaviors. Future research may benefit from securing data via other methods such as in-lab observations. Further, most studies rely on correlational data and, therefore, cannot determine causality. Future research may benefit from experimental designs with higher internal validity.

Research on the adaptive function of oral sex is in its early stages, and future research is needed to replicate current findings, test some of the hypotheses more directly, and expand this field into other areas of psychological research. For example, past studies have found that the oral sex performance is explained, in part, by individual differences such as men's agreeableness (Pham et al. 2015) and women's conscientiousness (Sela et al. 2015). Additionally, because oral sex is extremely common among other species, further investigation is needed to understand the function of oral sex among species that do not regularly participate in pair-bonding (i.e., mating systems in which mate retention has little adaptive value).

Conclusion

Oral sex is most common in long-term relationships and is linked to relationship satisfaction and

to partner's risk of infidelity. Several nonmutually exclusive functional hypotheses have been proposed and tested for oral sex: mate retention, infidelity-detection, sperm-competition tactic of ejaculate adjustment, fertility detection, and paternal investment detection. Given that each hypothesis has at least some supporting evidence, it is likely that more than one is needed to explain this common sexual behavior in humans. Further experiments are needed before causal statements can be made. The ubiquity of oral sex across cultures and across evolution warrant further investigation into its evolutionary significance.

Introduction

Kyle, 16 years old, and Sasha, 17 years old, have been dating for 6 months. They have decided to become more intimate and are planning to have oral sex. Sasha remembers hearing about using

male condoms but doesn't think they need to use anything if she were to receive oral sex.

A few weeks later, Sasha sees her doctor for a check-up. Her doctor asks about whether Sasha has had sex yet. Sasha says no, since she doesn't think oral sex counts. Her doctor reviews types of birth control and encourages Sasha to make an appointment to discuss her options to avoid unintended pregnancy, before becoming sexually active.

Despite oral sex being the most common form of sexual behavior among adolescents, the scenario above is unfortunately very common. While associated with decreased risks of acquiring a sexually transmitted infection (STI) and pregnancy, oral sex is not risk free and can have negative consequences related to health, social, and emotional wellbeing; however, many youth do not understand the risks and don't seek advice or protection. In this chapter, we will review epidemiologic data on oral sex among adolescents and young adults overall and by demographic factors, discuss health and social factors associated with oral sex, and identify reasons why adolescents have oral sex. We end with an important discussion of the importance of health care providers, educators, and parents talking to adolescents and young adults about oral sex.

Rates of Oral Sex, Overall and by Demographic Factors

Based on the most recent data on oral sex, from 2012, 66% of females aged 15–24 years had ever engaged in oral sex with an opposite-sex partner (65% for males). In comparison, 67% of females in this same age group have had vaginal sex. There were variations by sex, with 49% of adolescent males (ages 15–19 years old) having ever had oral sex; 35% had given and 47% had received oral sex. Among adolescent females, 48% reported ever having oral sex with an opposite sex partner; 41% had given oral sex, and 43% had received oral sex. Prevalence of oral sex was higher among young adults (20–24 years old)

with 85% of females and 82% of males reporting having ever had oral sex. In comparison, national data from 2012 show that 47% of female and 44% of male adolescents had ever had vaginal intercourse. Prevalence was higher among young adult females and males (87% and 85%, respectively) (Copen et al. 2012). Similar trends were observed in other datasets (Halpern and Haydon 2012; Herbenick et al. 2010).

A more recent study on adolescent and young adult oral sex patterns found that the percent of females aged 15–24 years who ever engaged in oral sex was lower for both giving (59.6% from 2007 to 2010 compared to 58.6% from 2011 to 2015) and receiving (62.2% to 60.4%). Percentages increased for males for both ever having given (53.9% to 55.4%) and received (62.9% to 64.6%) oral sex. Racial and ethnic minorities were less likely to have given or received oral sex (Holway and Hernandez 2017).

Racial and ethnic variation in prevalence of any oral sex exist among 15–24-year-olds. White females reported ever having engaged in oral sex most often (69%), followed by black females (63%), and then Hispanic females (59%). There were no differences by race or ethnicity among 15–24-year-old males who had ever had oral sex. There were racial/ethnic differences among males who had reported giving oral sex, with white males having engaged most often (60%), followed by Hispanic males (51%) and black males (44%) (Copen et al. 2012).

Is there a relationship between initiation of oral sex and initiation of vaginal sex? The most recent data, from 2007 to 2010, show that 5.1% of females and 6.5% of males aged 15–24 years had oral sex but had not yet had vaginal sex. Of those who had both vaginal and oral sex within this same age group, percentages were nearly identical for females who had oral sex before having vaginal sex as vaginal sex before oral sex (26% and 27%, respectively). There were no differences in percentages reported among males, with 24% of males having oral sex first and 24% reporting having had vaginal sex first. Data from a longitudinal study of adolescents found that

18.3% of males and 11.0% of females reported initiating oral sex first, while 23.6% and 43.3% (males and females respectively) reported initiating vaginal sex first. Engaging in both behaviors within the same year was also common (38.4% among males, 26.6% among females) (Halpern and Haydon 2012). Another longitudinal study showed that adolescents who have had oral sex in the first 2 years of high school were significantly more likely to progress to vaginal sex than adolescents without oral sex experience or those who had oral sex later in their high school tenure (Song and Halpern-Felsher 2011).

How much should we worry about adolescent oral sex behaviors? While those who engage in oral sex avoid the risk of pregnancy, engaging in oral sex is not risk free. Transmission of sexually transmitted infections (STIs) including herpes, human papilloma virus (HPV), human immunodeficiency virus (HIV), gonorrhea, chlamydia, syphilis, and trichomoniasis have all been reported (Ballini et al. 2012; Edwards and Carne 1998; CDC 2017). Because of this risk, health care providers recommend using a barrier method (e.g., condoms or dental dams) when having oral sex.

Given the known health risks associated with oral sex, why do adolescents decide to have oral sex? Explanations of adolescent engagement in oral sex point to several factors, including social and attitudinal factors. These are described next.

One possible explanation for why so many adolescents have oral sex is that they often do not consider oral sex to be sex, and thus do not believe that oral sex confers the same health outcomes as those resulting from vaginal sex. Compared to vaginal sex, adolescents perceive oral sex as significantly less risky with respect to health risks such as STIs including HIV. Adolescents also believe that oral sex is less risky with respect to social and emotional outcomes. For example, adolescents report that having oral sex is less likely to get them into trouble, result in a bad reputation, produce feelings of guilt, or result in them feeling bad about themselves. Moreover, 14% of adolescents believe that there is zero chance of contracting chlamydia from oral sex, and 13%

believe there is zero chance of getting HIV from oral sex. In comparison, 1% perceive zero risk of contracting chlamydia and 2% perceive zero risk of getting HIV from having vaginal sex. Adolescents also believe that oral sex is more prevalent and more acceptable for people of their age, and doesn't impinge on moral or religious values as much as vaginal sex (Halpern-Felsher et al. 2005). Nevertheless, adolescents who indicate that religion is important to them are also less likely to have oral sex (Holway and Hernandez 2017).

A qualitative study of adolescents provided further insight into the reasons why they have oral sex. The main reasons adolescents cited were wanting pleasure, improving their relationship, gaining popularity, bettering their reputation, curiosity and wanting the experience, feeling it is less risky than vaginal sex, and peer pressure. Girls were more likely than boys to indicate personal benefits from having oral sex (e.g., it will improve my relationship, provide pleasure) and social factors (e.g., peer pressure), and to be concerned about fear or being forced to have oral sex (Cornell and Halpern-Felsher 2006). Oral sex is more common among adolescents who are in a committed relationship, which might explain in part why they don't use condoms during oral sex (Holway and Hernandez 2017).

These perceptions and misperceptions about oral sex, and oral compared to vaginal sex, are important given evidence that there is a strong link between perceptions and behavior. Perceptions of positive and beneficial outcomes resulting from oral sex are more likely to influence behavior than the threat of negative health outcomes. Interestingly, data on adolescents' actual reported consequences of having oral sex compared to vaginal sex mirror their perceptions. Adolescents who have had oral sex have indeed experienced fewer health consequences than those having had vaginal sex, including STIs, pregnancy, or HIV. Those with oral sex experience were also less likely to report feeling guilty, having their relationship worsen, or getting into trouble, compared to those with vaginal sex experience (Brady and Halpern-Felsher 2007).

Conclusion

Oral sex is the most common form of sexual behavior among adolescents, with adolescents having oral sex largely to avoid the health risks associated with vaginal sex, while still gaining pleasure and social benefits, such as maintaining or improving relationships. Despite the popularity of oral sex, most research, health messages, and prevention efforts in reproductive health focus predominately on vaginal intercourse including pregnancy and STI prevention. As such, adolescents receive limited education about oral sex, including the possible risk of STIs including HIV. Furthermore, they receive little information about the social and emotional outcomes that can result from engaging in oral sex.

Turning back to Kyle and Sasha, it is imperative that health care providers screen, counsel, and educate adolescents about oral sex specifically, not just sex in general or vaginal sex. Adolescents need anticipatory guidance around oral sex, and the progression from oral to vaginal sex. Further, parents and health educators should include discussions of oral sex when they talk to adolescents about sex, including information and discussion of related health, social, and emotional outcomes. Conversations must also go beyond a discussion of the health risks to also include guidance on how to navigate peers and partners as they make decisions about whether or not to have oral, or vaginal, sex.

Oral Sex as Mate Retention

Yael Sela and Michael N. Pham

Department of Psychology, Oakland University,
Rochester, MI, USA

Definition

Sexual activity in which an individual uses their mouth to stimulate the genitals of their long-term partner in an effort to retain that partner.

Introduction

People in long-term relationships perform a diverse array of behaviors, the motivation for which developed over evolutionary history, to minimize the likelihood of their partner's infidelity. Oral sex performed on a long-term partner may be one such behavior, as reviewed below.

Oral Sex as Mate Retention

Humans may have evolved psychological mechanisms that motivate the performance of "mate retention" – behaviors that lessen the risk of partner infidelity and desertion (see *Mate Retention*). Buss (1988) identified 104 acts of mate retention, and these were later grouped into two superordinate "domains": Cost-Inflicting mate retention behaviors and Benefit-Provisioning mate retention behaviors. Behaviors in the Cost-Inflicting domain reduce the risk of partner infidelity by lowering a partner's self-esteem, thereby causing that partner to feel unworthy of the current relationship, but especially of any other potential relationship. In contrast, behaviors in the Benefit-Provisioning domain reduce the risk of partner infidelity by increasing a partner's relationship satisfaction. The evidence that oral sex is a mate retention behavior, in general, and a Benefit-Provisioning behavior, in particular, is reviewed.

Oral sex is a common sexual activity (e.g., Santtila et al. 2008; Vannier and O'Sullivan

2012) that is linked with sexual satisfaction and relationship satisfaction. Men are equally likely to report their female partner performing oral sex on them (i.e., *fellatio*) and performing oral sex on their female partner (i.e., *cunnilingus*) at their most recent sexual encounter as women are to report performing fellatio and receiving cunnilingus (Vannier and O'Sullivan 2012). Most men and women report experiencing oral sex at least once in their life, and both desire to experience oral sex (Santtila et al. 2008). Men (relative to women) desire oral sex more often, and men's (but not women's) relationship satisfaction is positively correlated with their actual frequency of experiencing oral sex (e.g., Santtila et al. 2008). Notably, men's likelihood of orgasm at last copulation does *not* depend on the performance of fellatio, but women are more likely to experience an orgasm if they receive cunnilingus than if they do not receive cunnilingus (Richters et al. 2006), and female orgasm is positively associated with women's relationship satisfaction.

Oral Sex as Benefit-Provisioning Mate Retention

Men may perform cunnilingus as a means of mate retention. Men at greater risk of a partner's infidelity report greater interest in, and spend more time, performing cunnilingus on their partner (Pham and Shackelford 2013b). In contrast, men do not typically perform cunnilingus on a woman during a casual, sexual encounter (i.e. "a one-night stand"), a mating context that presents no risk of long-term partner infidelity. Men who report performing more mate retention behaviors, in general, also report greater interest in, and spend more time, performing cunnilingus on their partner (Pham et al. 2013b).

Men may perform oral sex as a Benefit-Provisioning (as opposed to Cost-Inflicting) mate retention behavior, in particular. Women who receive cunnilingus from their partner, relative to women who do not, report greater relationship satisfaction (e.g., Santtila et al. 2008). Because greater partner relationship satisfaction is an outcome of Benefit-Provisioning mate

retention, Pham and Shackelford (2013a) hypothesized and documented that men perform cunnilingus on their partner as part of a Benefit-Provisioning mate retention strategy. Specifically, men who report performing more frequent Benefit-Provisioning mate retention behaviors, but *not* more frequent Cost-Inflicting mate retention behaviors, also report greater interest in, and spend more time, performing cunnilingus on their partner. In fact, men who report performing more Cost-Inflicting mate retention behaviors also report less interest in performing cunnilingus on their partner.

Similar results have been documented in women. Women, like men, are more likely to engage in oral sex within a committed relationship (vs. casual sexual encounter; Vannier and O'Sullivan 2012), a mating context that would elicit mate retention behavior. Thus, Sela, Pham, Shackelford, and Euler (2015) hypothesized and documented that women who report performing more Benefit-Provisioning mate retention behaviors also report greater interest in, and spend more time, performing fellatio on their partner. However, women's interest in, and time spent, performing fellatio on their partner is not related to women's frequency of *overall* mate retention behaviors.

Limitations and Future Directions

There are limitations of the two main studies that directly test the hypothesis that oral sex is a mate retention behavior (Pham and Shackelford 2013a; Sela, Pham, Shackelford, & Euler, 2015). First, these studies relied on self-reported mate retention behaviors. People may underreport the frequency with which they perform socially undesirable behaviors (e.g., "I told others of my same sex that my partner might have a sexually transmitted disease"). However, both men's and women's self-reports of their mate retention behaviors have been shown to positively correlate with their partner's reports of these behaviors. Nevertheless, future research may benefit from securing reports from both partners. Further, the two main studies rely on

correlational data and, therefore, cannot determine causality.

Another limitation is that both studies explain just a small amount of variance in individuals' reports of their mate retention behaviors and oral sex behaviors. Although these studies have documented relationships between these behaviors in both men and women, they offer only a first step toward identifying a function for oral sex and only within a committed relationship.

Research on oral sex as a mate retention behavior is preliminary, and future research is needed to expand this field into other areas of psychological research. For example, past studies have found that the association between oral sex and mate retention behavior is explained, in part, by individual differences such as men's Agreeableness (Pham et al. 2015) and women's conscientiousness (Sela, Pham, Shackelford, & Zielger-Hill, 2015). Additionally, because oral sex is extremely common among other species, further investigation is needed to understand the function of oral sex among species that do not regularly participate in pair-bonding (i.e., mating systems in which mate retention has little adaptive value).

Conclusion

Preliminary evidence supports the notion that men and women perform oral sex on their partner as part of a Benefit-Provisioning mate retention strategy. Receiving oral sex from a partner is associated with increased satisfaction and thus may lessen the likelihood of partner infidelity or defection. Individual differences may help further explain why some people perform oral sex as part of a Benefit-Provisioning mate retention strategy, and this is one of several promising areas for future investigations.

Organized-Insecure Attachment

Tommie Forslund¹ and Pehr Granqvist²

¹Uppsala University, Uppsala, Sweden

²Stockholm University, Stockholm, Sweden

Definition

Organized-insecure attachment denotes patterns of attachment behavior in relation to the caregiver that are organized but which, in comparison to secure attachment, are inflexible and suboptimal (e.g., lower in quality). The less than optimal organization is seen in a decreased ability to use the caregiver as a secure base to explore the environment from and as a safe haven to return to for comfort and protection when distressed. The insecure-avoidant pattern is particularly characterized by a decreased ability to turn to the caregiver for support when distressed (e.g., as a safe haven), with these children showing avoidant

behaviors such as turning away from and/or ignoring their caregiver in the strange situation procedure (termed a “minimizing strategy”). The insecure-ambivalent/resistant pattern is characterized by a decreased ability to use the caregiver as a reference point for exploration of the environment (e.g., as a secure base), with these children showing high levels of negative affect and wanting comfort from the caregiver together with an inability to be soothed by the contact and rejections of the caregivers’ bids to soothe the child (termed a “maximizing strategy”). Although these patterns are considered insecure, the characteristic behavior in relation to the caregiver following activation of the attachment system is nonetheless predictable and considered functional in the sense that it typically results in maintenance of some level of proximity to the caregivers, hence the term organized-insecure. Organized-insecure attachment is reliably predicted by patterns of caregiving that are insensitive (e.g., rejecting and inconsistent caregiving) but not frightening.

Introduction

John Bowlby, a British psychoanalyst and child psychiatrist (see ► [“John Bowlby: Pioneer of Attachment Theory”](#)), was unsatisfied with the explanations of attachment available at the time, which deemed children’s attachments to their caregivers a secondary result of other mechanisms, such as children’s drives and/or feeding (see ► [“Psychodynamic Foundations”](#)). Seeking an alternative explanation for the phenomenon of attachment, Bowlby founded attachment theory by drawing from multiple scientific traditions, most notably ethology, cybernetics, and cognitive theory (see ► [“Evolutionary Foundations of the Attachment System and Its Functions”](#)).

Specifically, Bowlby (1982) argued that humans come into the world endowed with an attachment behavioral system (and attachment behaviors) which function is maintain proximity to caregivers and which was retained through natural selection as it was associated with increased chances of survival against predators and other natural dangers (see ► [“Infant](#)

[Survival”](#)). Thus, children (the weaker, smaller part) form attachment bonds to caregivers (the stronger, wiser part[s]) who are sufficiently available and responding to their signals (not the other way around; see ► [“Offspring–Parent Attachment”](#)).

Bowlby, having to contest the theories of attachment available at the time, and formulate a new, scientifically based explanation for the phenomenon of attachment, devoted a great deal of effort into delineating the normative aspects of attachment. Subsequently, although he believed that there are individual variations in the “quality” of children’s attachment, which he argued were manifested in cognitive affective representations of self and others (e.g., termed “internal working models” [IWMs]; see ► [“Individual Variations in Attachment”](#) and ► [“Evolutionary Foundations of the Attachment System and Its Functions”](#); Bowlby 1982), formed from the history of interactions with the caregivers, he did not get around to systematizing these variations. Lacking an empirical method for examining inter-individual variations in quality of attachment, he instead focused his efforts on the need for a continuously available and responsive caregiver and the negative effects following separations and or loss of caregivers, which were readily observable in the post-world war era (e.g., Bowlby 1982).

Attachment theory therefore owes much to his close collaborator Mary Ainsworth and her colleagues and students, most notably Mary Main, for the subsequent mapping of systematic individual differences in attachment quality and organization (Ainsworth et al. 1978; Main and Solomon 1990). Drawing on Bowlby’s ideas about the interaction between the attachment system and other behavioral systems, most notably the exploratory system and the fear system, Ainsworth devised a semi-structured laboratory observation called the “strange situation procedure” (SSP), which enabled examination of the organization of behavior that children (aged 12–18 months) strike between their attachment needs and those of exploration. That is, the quality of children’s attachments to their caregivers cannot be indexed by any single behavior, but is rather seen in the organization of behavior in relation to

the caregiver (see ► [“Individual Variations in Attachment”](#)).

Ainsworth and her colleagues discovered three organized patterns of attachment. The first pattern, secure attachment, is considered the optimal organization of behavior (e.g., of highest quality) as observed in these children’s ability to use the caregiver as a secure base and a safe haven (see ► [“Secure Attachment”](#) and ► [“Individual Variations in Attachment”](#)). The other two organized patterns of attachment that Ainsworth discovered, which are considered less than optimal, yet organized, are described below (see ► [“Disorganized Attachment and Reactive Attachment Disorder”](#) for children who cannot maintain an organized strategy of attachment behavior and children showing profound difficulties forming attachments).

Insecure-Avoidant Attachment

Behavioral description. Avoidant children show a distinct pattern in the SSP which although viewed as insecure is nonetheless organized (“organized-insecure”). Although initially exploring the play material in the SSP, avoidant children’s play often lacks the complexity shown by secure children, being more stereotypic and shallow. Avoidant children also tend to share their experiences with the caregiver less often than secure children do, show less positive affect in relation to the caregiver, and do not involve their caregiver in play as often as secure children do. That is, avoidant children’s ability to use the caregiver as a secure base from which to explore the environment seems to be impaired.

Upon entry of the stranger, avoidant children are less often seen to retreat to their caregiver for protection and comfort. Avoidant children typically do not protest the separations and typically show only a little or no signaling behaviors such as crying and/or calling for the caregiver during the separations. In the reunion episodes, it is particularly characteristic of avoidant children to avert their gaze from the caregiver and/or turn and move away from the caregiver (e.g., avoidant behaviors). Indeed, they may actively ignore the

caregiver for an extended time, even if the caregiver is trying to gain the child’s attention. Their level of proximity-seeking and contact-maintaining behavior is thus typically low, and although some resistance may be present (particularly if the caregiver insists on interaction), it is not as characteristic as their avoidant behavior. In comparison to secure children, avoidant children do not show the same striking specificity of preference for the caregiver to the stranger.

Predictors of avoidant attachment and developmental correlates. Importantly, the avoidant pattern of behavior in relation to the caregiver in the SSP cannot be explained by stable dispositions such as temperament (Vaughn et al. 2008). Indeed, research examining physiological stress responses in children during and after the SSP has shown that avoidant children are stressed, as measured by galvanic skin response, heart rate, and cortisol level. Yet, they do not show an optimal ability to use their caregiver as a safe haven to return to for comfort when they are distressed. Ainsworth and her colleagues, and the research that subsequently followed (Isabella and Belsky 1991), have shown that avoidant children tend to have caregivers who are less sensitive than caregivers of secure children. Specifically, the caregivers of avoidant children more often “reject” their children’s bids for proximity and comfort when distressed and have difficulties being in close bodily contact with their children (Ainsworth et al. 1978).

Meta-analytical research has found that about 20 % of children in normative samples tend to be avoidant (van IJzendoorn and Sagi 1999). The avoidant pattern is often referred to as a “minimizing strategy,” denoting these children’s limited display of attachment behaviors and affect in relation to the caregivers (Cassidy 1994). However, although regarded as a suboptimal organization of behavior, it is important to note that avoidant children manage to maintain some proximity to their caregivers without risking further rejection and potential abandonment (Main 1981; Simpson and Belsky 2008). The avoidant strategy has, however, been found to constitute a risk factor for maladaptive development, for example, in

the form of higher levels of later behavior problems (see ► [“Effects of Attachment Quality and Organization”](#)) and suboptimal functioning in adult relationships (see ► [“Attachment in Adulthood”](#)).

Ambivalent/Resistant Attachment

Behavioral description. Ainsworth and colleagues (Ainsworth et al. 1978) identified a second pattern of organized-insecure attachment, which they termed ambivalent (or resistant) attachment. These children often have difficulties with exploration in the SSP, and it is not uncommon for them to show negative affect and distress even before the stranger enters the room, demanding attention by and proximity to the caregiver. These children often retreat to the caregiver when the stranger enters and show limited acceptance of interaction with the stranger. Thus, as avoidant children, these children also show an impairment in the ability to use the caregiver as a secure base for exploration. The ambivalent children typically show intense negative affect during the separation episodes and markedly reject the stranger’s efforts to comfort the child.

In the reunion episodes, they often show moderate to high levels of proximity-seeking and contact-maintaining behaviors together with low levels of avoidant behaviors. Their behavior is however particularly characterized by an inability to be soothed by the caregiver’s overtures, in combination with angry behaviors toward the caregiver (resistant behaviors). Such behaviors include temper tantrums, angrily arching the back when in close contact with the caregiver, wanting to be put down just to become more angry if put down and then wanting to be picked up again, batting away toys, etc. Thus, they often signal a desire to the caregiver for comfort, as do secure children, but they are not effective in being comforted by this contact, indicating that their caregiver is insufficient as a safe haven.

Predictors of ambivalent/resistant attachment and developmental correlates. Ainsworth and colleagues, and research that followed, have found that these children tend to have caregivers

who are inconsistent in their sensitivity, sometimes responding sensitively and sometimes not (Ainsworth et al. 1978; Cassidy and Berlin 1994). As for avoidant children, the pattern shown by ambivalent children is thought to be suboptimal yet an organized strategy that results in proximity to the caregiver. This strategy has been described as a “maximizing” strategy (Cassidy 1994). That is, due to the inconsistent responding by the attachment figure, these children may come to heighten the activation of the attachment system to increase the chances that the caregiver will respond should there be danger. Evolutionarily, this may have resulted in increased attention by and proximity to the caregiver, lowering the risk of being exposed to predators and other natural dangers (Main 1981; Simpson and Belsky 2008). Meta-analytical findings have indicated that about 5–10 % percent of children in normative samples are ambivalently attached (van IJzendoorn and Sagi 1999). As for avoidant children, this pattern is also associated with an increased risk for maladaptive development, including higher levels of behavior problems (see ► [“Effects of Attachment Quality and Organization”](#)) and lower functioning in adult relationships (see ► [“Attachment in Adulthood”](#)).

Missing pieces and current research. The significant but lower than expected correlation between sensitivity and attachment found in meta-analytical research (De Wollf and van IJzendoorn 1997) has yielded interest in other dimensions of caregiving besides sensitivity, such as mind-mindedness and reflective functioning (see ► [“Secure Attachment”](#)). Research is also trying to disambiguate the mediating factor (s) between insecure attachment and maladaptive development (see ► [“Effects of Attachment Quality and Organization”](#)). Lastly, research is also examining variations in attachment quality and organization in relation to adult functioning (see ► [“Adult Attachment”](#)).

Conclusion

Organized-insecure attachment denotes suboptimal yet organized patterns of attachment

behavior in relation to the caregiver (e.g., insecure-avoidant attachment, insecure-ambivalent/resistant attachment), wherein children's ability to use the caregiver as a secure base and a safe haven is impaired following insensitive caregiving on behalf of the caregiver. The organized-insecure patterns of attachment were discovered by Ainsworth using Bowlby's ethological approach, theoretically following Bowlby's ideas regarding the workings of the attachment system and its interaction with other behavioral systems.

Orgasm

Talia Shirazi and David A. Puts
Department of Anthropology, The Pennsylvania State University, University Park, PA, USA

Synonyms

Climax; Sexual response

Definition

A sexual climax typically experienced as a result of sexual stimulation, accompanied by involuntary muscle contractions and endorphin release.

Introduction

Orgasm is typically experienced as a sexual climax between the plateau and resolution phases of the human sexual response cycle (Masters and Johnson 1966). Whether the stimulation experienced during solitary or paired sexual behavior is induced manually, orally, or through the use of an object, orgasm in men is most reliably achieved through direct penile stimulation and in women through direct clitoral stimulation. Though there exists substantial overlap in the physiological and psychological sequelae of orgasm between the sexes, copulatory orgasm may serve different evolutionary functions in men and women. While men's copulatory orgasm is necessary for reproductive success, it is unclear whether women's copulatory orgasm is an adaptive mate-choice mechanism or a by-product of developmental processes shared with males.

Physiological and Psychological Effects of Orgasm

The physiological changes accompanying orgasm include accelerated heart rate, increased blood pressure, and pelvic muscle contractions (Masters and Johnson 1966). In men, muscle contractions in the penis and anal sphincter are typically accompanied by ejaculation, which function in sperm transfer during copulation. Women experience muscle contractions in the uterus, vagina, and anal sphincter during orgasm, which may by several mechanisms increase sperm retention and facilitate conception (Levin 2011; Lloyd 2005; Puts et al. 2012). These perceptible physiological changes are accompanied by differential patterns of neuronal activation in the orbitofrontal cortex, cerebellum, and paraventricular nucleus (e.g., Georgiadis et al. 2009), the latter of which

modulates the release of oxytocin (OXT), a hormone implicated in human pair-bonding.

It may be because of these similar patterns of neuronal activation that the psychological experience of orgasm is similar for men and women. Written descriptions of orgasmic experiences do not differ significantly between men and women, though recent studies suggest that women may subjectively rate orgasms as more intense than do men. In both sexes, orgasm is described as satisfying and rewarding, which may encourage men and women to engage in behaviors that could result in orgasm and, in the case of copulation, to engage in copulation until orgasm is achieved.

As ejaculation is required for reproductive success in men, the ability to do so during intercourse has likely been under strong selective pressure throughout human evolution. More than 75 % of men report experiencing orgasm during every act of intercourse, and primary anorgasmia (never having experienced orgasm) in men is rare. By contrast, the prevalence of primary anorgasmia in women is much higher, with about 5–10 % of women never having experienced orgasm. Indeed, copulatory orgasm is experienced much less frequently in women than in men, with approximately 25 % of women always and 33 % never experiencing copulatory orgasm (Lloyd 2005).

Orgasm as an Adaptation

It has been suggested that orgasm serves a mate-choice function in women (Smith 1984). Orgasm may facilitate fertilization by high-quality mates by stimulating ejaculation, reinforcing copulation until ejaculation occurs, promoting repeated copulation with the same males, and inducing peristaltic contractions of the uterus and oviducts, which transport sperm toward the ovum (reviewed in Puts et al. 2012; Wheatley and Puts 2015).

Women may be more likely to experience orgasm during copulation with men possessing putative markers of genetic fitness (Smith 1984), such as facial attractiveness, facial masculinity, and low fluctuating asymmetry. Several studies

have found a positive association between these traits and women's frequency of copulatory orgasm, even when controlling for potential confounds such as relationship duration and relationship satisfaction (reviewed in Puts et al. 2012; Wheatley and Puts 2015). Women's frequency of copulatory orgasm may also be positively associated with the major histocompatibility complex (MHC) genetic compatibility of their male sexual partners, in that that conception with MHC-discordant men should produce offspring with strong adaptive immunity. Interestingly, this association was only found when women were in the fertile phase of the menstrual cycle (Garver-Apgar et al. 2006). Thus, there may exist a largely unexplored interaction between women's fertility and markers of men's genetic quality and compatibility in predicting the frequency of women's copulatory orgasm. More generally, women's greater difficulty in achieving orgasm may reflect their overall greater choosiness over sexual partners resulting from their greater investment in offspring (Symons 1979).

Women's copulatory orgasm may also serve a different adaptive purpose by facilitating long-term pair-bonding with men who are caring and would invest in offspring (Hamburg 1978). Some studies have found positive associations between women's frequency of copulatory orgasm and numerous indices of relationship satisfaction. More frequent copulatory orgasm, and concomitantly, more frequent OXT release, may facilitate women's desire to form pair-bonds with men who are perceived as caring, attentive, and investing. However, evidence for this hypothesis is mixed (for reviews, see Lloyd 2005; Puts et al. 2012; Wheatley and Puts 2015).

Orgasm as a By-Product

Alternatively, women's orgasm may be a by-product of developmental processes shared with men and devoid of any adaptive function in women. Prior to the tenth week of gestation, male and female embryos are physically indistinguishable (Hamburg 1978). Sexual differentiation of external reproductive structures begins around

the tenth week of gestation, when a previously undifferentiated structure called the genital tubercle develops into either the penis or the clitoris, both of which contain nerve and erectile tissues involved in sexual response. The presence of these tissues is patently adaptive in men, as they are required for ejaculation and sperm delivery. Such tissues implicated in orgasm in women, however, may not serve any adaptive function, but may remain present due to sexually antagonistic selection (Symons 1979).

Proponents of this by-product hypothesis have argued that if women's copulatory orgasm was under selective pressure and conferred a reproductive advantage, the frequency distribution of women's copulatory orgasm should look similar to that of men's: a distribution with little variability and with the majority of women reporting experiencing orgasm reliably and frequently during copulation. On the one hand, the frequency distribution of women's copulatory orgasm is almost flat and highly variable, suggesting a potential lack of selective pressure on a specific behavioral phenotype (Lloyd 2005). On the other hand, if female orgasm were selected to function in mate choice, then it should be less reliably induced on average compared to orgasm in men and exhibit greater variability due to its contingency on the quality of women's mates (Puts et al. 2012). In addition, because ejaculation is essential for reproduction whereas female orgasm is not, selection should favor the tendency for men to more quickly and easily achieve orgasm compared to women.

Conclusion

Despite the fact that "no other human sexual topic has been the focus of so much speculation and hypothesizing" (Levin 2011), it remains equivocal whether women's copulatory orgasm is an adaptation or simply a developmental by-product. Studies linking copulatory orgasm frequency to markers of relationship quality have necessarily been correlational. Consequently, causal relationships between these variables, as well as the directionality of any relationships,

have not been established. In addition to investigating causality, perhaps through longitudinal studies and path analysis, future work should continue to explore associations between women's copulatory orgasm and other markers of partner's genetic fitness and investment. Additionally, research should examine potential interactions between such markers and women's conception risk within the ovulatory cycle in modulating copulatory orgasm. Finally, future research should continue to investigate whether women's orgasm promotes sperm transport and whether the occurrence of orgasm contributes to the probability that coitus will result in conception during fertile days of the ovulatory cycle.

Definition

Difficulty reaching or controlling orgasm by a man or woman. The problem may be characterized by an early, delayed, or absence of orgasm.

Introduction

In both the four-stage model of sexual response first proposed by Masters and Johnson (excitement, plateau, orgasm, resolution) and the three-stage model later adapted by Kaplan (1995) (desire, arousal, orgasm), orgasm represents a reproductive and psycho-behavioral endpoint. In both models, orgasm follows variable periods of intensifying sexual arousal. Both sexes experience intense pleasure throughout the body during orgasm, a phenomenon mediated by brain regions involved with reward and pleasure. Although in men ejaculation nearly always occurs concomitantly with orgasm, women exhibit no comparable external genital response. Women's orgasm is signaled by, among other responses, pelvic and anogenital contractions, typically lasting two to three times longer than men's (Masters and Johnson 1970).

For men, the two most common orgasmic disorders are premature ejaculation (PE; ejaculating shortly after or prior to partner penetration, before the male wishes, and to the point of distress or disruption of his and/or his partner's sexual experiences) and delayed/inhibited ejaculation (IE; difficult or impossible ejaculation and orgasm). Women, by contrast, are characterized by only one orgasmic disorder called female orgasmic disorder (FOD), which is similar to men's IE, as it is characterized by the recurrent difficulty in reaching orgasm after becoming sexually aroused. Each of these disorders is sometimes further categorized as lifelong versus acquired (i.e., after some period of normal function) or situational (in specific circumstances or with a specific partner) versus global (across all circumstances) and may result from a variety of etiologies ranging from biological to psychological or their combination.

Premature Ejaculation

PE is characterized by ejaculation prior to expectation or desire and usually within a minute or two of penetration. Early studies suggested prevalence rates of 20–30%, but more recent studies using

dysfunction-based criteria suggest rates closer to 5–10%. A variety of theories surround the etiology of PE, spanning from physiological and psychological to relational – most likely all are involved, although to different degrees. Contrary to initial suppositions, PE does not appear to be age related (Binik and Hall 2014).

Various physiological or pathophysiological factors may contribute to PE, including a genetic predisposition, an anomalous sympathetic nervous system, a heightened penile sensitivity, medications, or a lower ejaculatory threshold. While all may contribute to PE, no single factor appears most relevant. Rather, an inherent range for ejaculatory latencies exists such that some men are predisposed to ejaculate rapidly after penetration (e.g., within 1–2 min), while others take longer (e.g., 5–10 min), with latency shaped further by contextual factors (e.g., lack of privacy) to better predict the actual timing of ejaculation. Psychological and relationship factors may also play a role in PE, such as social and emotional issues (including anxiety) that contribute to negative and distracting thought patterns during sex that might impair ejaculatory control or difficulties with the partner such as anxiety derived from sexual aversion or lack of interest.

Treatment for PE may involve pharmacological and/or psychosexual strategies, but in either case, as PE is considered a couple's issue, a team approach including the partner is preferred. Pharmacological treatment typically includes daily or on-demand use of low-dose selective serotonergic reuptake inhibitors, similar to antidepressant medications, where discontinuation marks the return of the condition. As an alternative, men could use a condom or apply a local anesthetic (e.g., lidocaine) to their penis, thus attenuating sensory input and increasing the latency to ejaculation. A possible side effect of using local anesthetics includes diminished vaginal sensitivity.

Psychosexual counseling such as cognitive-behavioral techniques (CBT), psychoeducation, and relationship counseling are alternate treatments, with a focus on lowering male sexual arousal and development of greater ejaculatory

control. Depending on the severity of the PE condition, these methods may be used in conjunction with pharmacological approaches. Combined psychosexual counseling with pharmacological treatments may improve overall efficacy, enabling couples to quickly gain sexual confidence while learning various psycho-behavioral techniques (Rowland 2012).

Delayed/Inhibited Ejaculation

Inhibited (IE) or delayed ejaculation refers to a man's persistent delay in or absence of orgasm despite adequate sexual stimulation. Normative data suggest that most men ejaculate within about 5–10 min after penetration, and therefore men who take significantly longer or simply give up due to frustration or fatigue may be considered for an IE diagnosis. The prevalence of this dysfunction is estimated to range from 5 to 15%, with an increasing prevalence associated with age (Laumann et al. 1999; Perelman and Rowland 2008).

A variety of pathophysiological and psychological explanations may account for men experiencing IE. Men who have recently acquired IE after some period of normal ejaculatory function may suffer from a pathophysiological origin such as surgical complication in the pelvic region, neuropathy, or endocrine dysfunction. Although pharmacological treatments have not proven effective in treating IE, should any of the man's ongoing medications interfere with ejaculatory response (and many do), the medication could be altered.

Psychological explanations, more relevant to lifelong IE or IE that has developed over a period of years, tend to focus more on attitudes toward sexuality (e.g., a high degree of religious orthodoxy and sexual guilt), inadequate sexual arousal, and anxiety surrounding sexual performance. For example, some men who masturbate frequently may develop a routine of rapid, stereotypical stimulation that does not replicate

stimulation during intercourse. Other men may worry about their ability to satisfy their partner, leading to distraction from erotic sensations that lead to sufficiently intense arousal for ejaculation.

IE may be particularly frustrating when it interferes with a couple's plan for procreation, yet a team (couple) approach carried out with the guidance of a psychosexual counselor can often alleviate the problem. Depending on its etiology, various treatments can be considered, but autoerotic patterns (e.g., masturbation, use of erotic materials), relationship issues (e.g., the man may no longer find his partner sexually attractive), and quality of the couple's communication about sexual stimulation preferences usually need to be assessed. Understanding relationship factors, such as underlying tension between the couple from fear of pregnancy or unresolved anger/resentment toward the partner, is an important precondition to treatment. In such situations the man may be mentally unable to allow himself to ejaculate, so such issues need resolution before other concerns are addressed.

Most IE treatments have the goal of increasing or reestablishing high levels of arousal and/or decreasing anxiety that may distract from erotic stimulation. For example, a man suffering from lifelong IE (fairly rare) must first learn his arousal and ejaculatory patterns and be comfortable communicating these to his partner. This process may include solo and/or mutual masturbation, exploring sexual fantasies together, and transferring the consequent arousal to situations involving intercourse. If the man has previously been able to reach orgasm or is able to do so during masturbation, treatment will likely focus on masturbatory retraining and underlying relational issues. Where, for example, current masturbatory patterns and/or use of erotic/arousing materials is not well aligned with partnered behaviors during intercourse, the clinician may recommend discontinuation or alteration in masturbation patterns in order to increase arousal during intercourse. Because such strategies often focus heavily on

providing and sustaining the man's arousal, the partner may sometimes feel that her/his needs are being neglected, but she/he can be counseled that the situation is a temporary strategy to improve sexual satisfaction for both of them. In addition to increasing the man's arousal, focus on anxiety and distraction reduction that typically interfere with arousal typically occurs throughout the treatment process.

Female Orgasmic Disorder

Female orgasmic disorder (FOD) is defined as a woman's difficulty or inability to reach orgasm following adequate sexual arousal. For this diagnosis, the woman must be bothered by the condition, and the inability must be abnormal for the woman's age, sexual experience, and adequacy of stimulation. Regarding this last criterion, as many women who have difficulty reaching orgasm are insufficiently sexually aroused, such women are generally regarded as having an arousal phase issue rather than an orgasm problem. FOD is thought to be the second most frequent female sexual dysfunction, estimated to affect 10–35% of women. Yet only about half of these women report concomitant concern about their condition (Meana 2012).

As with the men's orgasmic phase disorders, a myriad of possible etiologies exists for FOD. Importantly, no easily identifiable cause or causes can be invoked to explain the disorder. However, in contrast with men's sexual disorders, psychological and relationship factors tend to predominate, although biological and pathophysiological factors should not be discounted. Endocrine levels, medical conditions, medications, and surgical side effects all have the potential to affect women's overall health, their general sexual functioning, and the ability to reach orgasm. For example, extreme variation in testosterone levels (very high or very low), menopause status, orgasm-inhibiting medications (e.g., antidepressants), surgical interventions, and various illnesses can

affect women's sexual function. Furthermore, such physical conditions may impart psychological effects on mood, anxiety, and self-concept, all of which may reduce sexual interest, engagement, and the potential for sexual arousal. Such straightforward relationships between psychological issues and sexual functioning can often be identified through clinical investigation. Aging is another biological factor likely to affect sexual and orgasmic response in women, more through sociocultural expectation than the aging process itself. As menopausal changes occur, an agist view deems her reproductively spent, a view that impacts self-esteem, confidence, and a sense of self-efficacy, all of which are important to a sexually satisfying relationship. As with men with IE, no pharmacological treatments are available for FOD. However, if a medication is suspected of inhibiting orgasm, a substitute may be considered.

Aside from biomedical etiologies, a vast number of psychological factors have the potential to impact women's sexual arousal and orgasmic response, some already mentioned above. For example, a woman's self-concept, self-image, and response to general life stressors may affect her sexual functioning, distracting her focus from the erotic stimulation of the sexual experience. Socioculturally derived negative attitudes toward sexuality, depression, and anxiety – whether from sex-specific factors during sex (e.g., pain or discomfort during intercourse) or from broader life challenges – may inhibit women's sexual desire/interest and/or distract them from otherwise pleasurable stimulation during intercourse. Important to most women's sexual engagement and response is the quality of their relationship with their partner – whether they feel comfortable, desired, and a sense of emotional intimacy with him/her. Underlying tension in the relationship and/or feelings of anger toward the partner often act as strong inhibitors of arousal and orgasmic response. Overall, women may attribute their difficulty to a variety of etiologies. These attributions may be complex and sometimes vague, but they often provide an important starting point for treatment.

Psychosexual counseling is usually the most effective treatment for FOD. Clinicians typically use a combination of education, communication improvement, and cognitive-behavioral therapy (CBT), methods that enable the woman to learn more about bodily sensations and pleasure, to reduce anxiety, and to communicate effectively and comfortably with her partner. Effective methods for reducing anxiety – often an important first step – include a progression from pleasurable nonsexual touching to sexual intercourse (sensitive focus) or relaxation techniques to work through a hierarchy of anxiety-provoking sexual situations (systematic desensitization). In contrast, directed masturbation training is typically intended to increase sexual arousal by helping the woman identify her pleasure points. Initially done as an exploratory solo exercise, once able to reach an orgasm, the woman communicates with and assists her partner regarding effective ways to maximize arousal. Kegel exercises – the repeated 3-sec tensing and relaxing of the muscles used to stop urinating – can sometimes facilitate movement toward arousal and orgasm in women and so may be considered in conjunction with any of these methods.

Conclusion

Etiology of orgasmic problems may be different for men and women, but for each sex, a mix of physiological, psychological, and relationship factors are implicated. Psychosexual therapy approaches can be effective in ameliorating the condition, sometimes in conjunction with pharmacological treatment.

Definition

Explanatory hypotheses based on evolutionary theories on the process of submission of women with a view to the control of female sexuality and reproduction.

Introduction

Because of the different reproductive strategies (and biological configurations) of males and females, females would be more selective and therefore a rare resource in society, and males would face greater intrasexual competition. This scenario would be the basis of the male motivation to control female sexuality, and it is called patriarchy (Smuts 1992, 1995). Female sexuality coercion strategies involve various forms of violence such as physical assault, rape, threats, and other forms of intimidation that result in the creation of hierarchical cultures based on male domination (Appel 2016; Smuts 1992).

The biologist Barbara Smuts (1995) proposes, based on the integration of primatology findings, six hypotheses that would describe which cultural practices would be at the base of the patriarchal social organizations: (1) reduction of the females' ability to form alliances; (2) strengthening of

alliances between males; (3) male monopoly of resources; (4) inequality of resources between males; (5) female engagement in behaviors of submission to the control of their sexuality; and (6) use of language for the propagation of ideologies.

Mechanisms of Control of Female Sexuality

One of the common features of patriarchal societies is the limitation of females' ability to form alliances with other females or to maintain ties with their relatives. It is very common, for example, that when entering adolescence, females of nonhuman primates leave their group and become part of neighboring groups (Smuts 1995). Among humans, women leave their community and move into their husband's group. This isolation of the female favors the occurrence of sexual coercion, with the male forcing the female into intercourse and controlling the female's movements. In many species of primates, females are more frequently assaulted during their fertile period by males seeking intercourse (Smuts and Smuts 1993) or even by their own partner, in case she is very close to another male of the group during the fertile period (Kummer 1968). In social organizations in which females remain with their original troop and maintain alliances with relatives, such as in groups of *Rhesus* monkeys, Old World Monkeys, and Olive Baboons, or in groups in which there is an alliance between females, as among bonobos, there is a low frequency of male aggression and sexual coercion. Among humans, there is plenty of evidence that single women or those attempting to subvert this system end up becoming easier targets of violence and punishment (Appel 2016).

The formation of alliances between males is another important element in the constitution of the patriarchal organization. These alliances would have a dual function. Within the group itself, they can be used to coerce females and are more powerful than lone males. In the relationship between groups, they have the function of facing threats from other groups, which increases the

protection of the group and the status of the male in his group (Smuts 1995). Females of nonhuman primates copulate with males that kill their offspring because it is likely to be a male with a high status, which increases the chances that their baby will not perish (Watts 1989).

The advent of agriculture and husbandry is another important event for the exercise of control over females, as it had the effect of allowing the accumulation of goods and resources. Male monopolization of these resources forces females to submit to males to obtain means of survival and to compete for partners with more resources.

The male monopoly of resources is not enough to ensure the status of males. There must be inequality in the amount of resources monopolized by each male so that the "richest" can excel in sexual selection. Considering that the generations maintain these inequalities, females gradually became more vulnerable in relation to a small group of powerful males. If the more "peripheral" men cannot oppose the power of the more dominant, women also reduce the possibilities of establishing reciprocal and advantageous alliances with those men (Smuts 1995). Friendly relationships with more peripheral or younger males are advantageous for females as they may reduce the vulnerability or harassment received from males, as observed in baboons (Smuts 1985, 1995). Among these primates, females perform several activities with one or two males (such as feeding and hygiene), and in return, they receive protection for themselves and their offspring. This scheme is hampered if there is too much inequality among males, since the fighting or protective power that peripheral males could offer gradually gets smaller. In societies such as human society, this power could be illustrated by money or control of resources such as land, water, or food.

Patriarchal structures are not just products of male behavior. Some female reproductive strategies reinforce patriarchy. When isolated and dispossessed of resources, there is increased competition among females; preference for powerful male in resources; and preference towards male descendants (Smuts 1995). Dickemann (1979) points that behaviors that increase the control of males and the

certainty of paternity over the woman favor the obtaining of rich partners. These behaviors can range from imprisonment to genital mutilation (infibulation) and are often supported by women to obtain compensatory benefits. Chigbu (2019) noted that women in peri-rural communities in Nigeria exhibit behaviors that hinder women's access to land tenure. When they inherit land, these women often transfer ownership or management to their siblings, which is seen as a way to please them, but they do not do the same with sisters. Moreover, when women express an interest in buying land for themselves, they are intimidated and embarrassed by other women to pass on possession of the land bought to their siblings.

Lastly, the evolution of language allows the establishment of an ideological field of domination that reinforces previous structures (Smuts 1995). Through it, different beliefs that reinforce men's control over women are propagated, strengthening the maintenance of patriarchal practices. The belief that many societies have that men can physically punish females for adultery or that women who are alone invite harassment are examples of these ideologies. These mechanisms seem to contribute to the maintenance of female behaviors that can reinforce patriarchy and to alliances and agreements for male domination over women (Smuts 1992).

Conclusion

Patriarchy can be considered the product of a set of proximal contingencies related intimately to the advent of agriculture and husbandry, whose purpose is to control female sexuality and reproduction with a view to increasing male fitness. The variety of human organizations and evidence of primate social behavior make it possible to assert that although patriarchy is widespread among known social organizations, it is not inevitable, but rather the fruit of these proximal selection contingencies that may vary across cultures and throughout history. Evolutionary theory may contribute to enriching discussions of power relations in feminist theses on gender inequity, since these theses also consider power relations and the

control of female sexuality as bases of the patriarchal structure (Smuts 1995).

Orrorin tugenensis

Brian Richmond

Division of Anthropology, American Museum of Natural History, New York, NY, USA

Definition

Orrorin tugenensis is the species name given in 2001 to fossils, from sites about six million years old in Tugen Hills in Kenya, that are thought to represent one of the very earliest members of the human lineage.

Introduction

At the turn of the millennium in 2000, a team led by French paleoanthropologists Brigitte Senut and Martin Pickford discovered a dozen fossil bones and jaw fragments of a previously unknown species in the Tugen Hills in central Kenya. The bones and teeth showed a combination of human and ape features not seen in any other species, leading them to name a new genus and species, *Orrorin tugenensis* (Senut et al. 2001). The name *Orrorin* means “original man” in the Tugen language, and Senut et al. noted that the pronunciation resembles the French word *aurore* meaning “dawn, daybreak,” both referring to the idea that this species lies at or near the beginning of the human family tree. The specific name *tugenensis* refers to the Tugen Hills where the fossils were discovered. Because it was discovered in 2000, it was nicknamed “Millennium Man” but this name is no longer widely used. At present, this is the only species placed in the genus *Orrorin*.

O. tugenensis remains one of two species (the other being *Sahelanthropus tchadensis*) that may be the oldest known species in the human family

tree (or “hominin,” the group describing all species that are more closely related to modern humans than to any other living species). Since its initial discovery, only a handful of additional fossils have been recovered, and more fieldwork is needed to expand what is known about this important species.

Sites: The fossils attributed to *O. tugenensis* came from four different sites in the Lukeino Formation, a geological formation spanning a time period from about 5.7–6.1 Ma (million years ago) (Pickford and Senut 2001). Most of the fossils were found at a site called Kapsomin; three other sites (Cheboit, Kapcheberek, and Aragai) each yielded one specimen attributed to *O. tugenensis*.

Key fossils: Every species has a “holotype” that represents the physical individual(s) on which the species name and definition are based. The holotype of *O. tugenensis* is specimen BAR 1000'00, consisting of left and right pieces of a mandible (lower jaw) preserving the back molars, or cheek teeth. Other fossils that are important to understanding the biology and behavior of *O. tugenensis* include BAR 1425'00, a right upper canine tooth; BAR1002'00, the top half of a femur (thigh bone; Fig. 1); BAR 1004'00, the lower portion of a right humerus (arm bone); BAR 349'00, a proximal phalanx (finger bone); and BAR 1901'01, a pollical distal phalanx (thumb tip bone).

Characteristic anatomy: Senut et al. (2001) make the case that *O. tugenensis* is distinct enough from other known hominins to justify the creation of a new genus and species name. The cheek teeth of *O. tugenensis* are smaller and less elongated than those of *Australopithecus* and have thicker enamel than those of *Ardipithecus*. The femur has a large head, long neck, and wide shaft similar to other hominins, but also shares primitive features with fossil Miocene apes (Sergio Almécija et al. 2013; Richmond and Jungers 2008). Its body size was similar to the size of a small chimpanzee (Grabowski et al. 2015).

Behavior: The anatomy of *O. tugenensis* sheds light on its biology and behavior. The low, rounded cusps on the cheek teeth suggest that,

***Orrorin tugenensis*,**

Fig. 1 Back view of BAR1002'00, the top half of a femur (thigh bone) belonging to *Orrorin tugenensis*. The long, narrow neck, large head, wide shaft, groove (for the *obturator externus* muscle) along the neck, and line (proto-*linea aspera*) on the back of the shaft are features related to upright, two-legged stance and linked to the human family tree

like other higher primates with similar tooth structure, *Orrorin*'s diet included fruit, nuts, seeds, leaves, insects, and occasional small animals. Its thicker enamel suggests that it was equipped to handle harder foods than those in the typical diets of most modern apes and monkeys.

O. tugenensis climbed trees but shows signs of walking upright on the ground more intensively than any living ape. Evidence for tree climbing comes from its humerus (arm) anatomy and curved finger bones (Richmond and Jungers 2008; Senut et al. 2001). Scholars agree that upright bipedalism (on two legs) was an important part of its posture and movement patterns, but it remains unknown exactly how well it was adapted to bipedalism. The thigh bone has a long, narrow neck, wide shaft, groove (for the *obturator externus* muscle) along the neck, line (proto-*linea aspera*) on the back of the shaft (Fig. 1), and aspects of internal bone anatomy; these point to similarities in function shared with later hominins such as *Australopithecus*, but some features are more ape-like (Sergio Almécija

et al. 2013; Galik et al. 2004; Richmond and Jungers 2008). A more complete picture of its bipedal behavior and adaptation is limited by the lack of evidence about other parts of its anatomy.

Surprisingly, the thumb tip bone (distal phalanx) appears more like a modern human thumb than the thumbs of *Australopithecus* that lived millions of years later in time (S. Almécija et al. 2010). At 6 Ma, *O. tugenensis* appeared to have better precision grasping capabilities than seen in any living ape and suggests that manual dexterity played an important role in the lives of the earliest hominins.

Clues about social behavior come from the canine teeth. In most higher primates, the upper canine teeth are long, sharpen against the lower teeth, and are used to communicate aggression and occasionally to fight, especially in male-male competition over social rank and access to females. *O. tugenensis*, like all later hominins, has a small canine that lacks a wear facet (Senut et al. 2001), showing that it was not “sharpened” against the lower teeth and probably not used, at least to the degree in most higher primates, in competitive social settings. There are many hypotheses regarding why, when, and how these social strategies changed during human evolution.

Conclusion

O. tugenensis has several important implications for our understanding of human origins, although these remain tentative until a more thorough body of fossil evidence is found. First, it suggests that the last common ancestor of humans and chimpanzees split into their separate lineages earlier than 6 Ma, consistent with other evidence from the fossil record and some studies of the genetic differences between humans and chimpanzees (Pozzi et al. 2014). Second, it supports Charles Darwin’s speculation that the human lineage began in Africa (Darwin 1871); in Darwin’s time, there was no known early human or African ape fossil record, so this idea was based on the observations that anatomy suggests a close relationship between humans and African apes and that Africa is the only place that humans,

chimpanzees, and gorillas inhabit today. However, this does not preclude the possibility that Eurasia was home to earlier ancestors of African apes and humans, where a diverse group of great apes lived in the Miocene and could have expanded into Africa during times when the connections between Africa and Eurasia were much more extensive than they are today. Finally, *O. tugenensis* shows that, at about 6 Ma, the earliest members of the human lineage had very few of the characteristics that make humans distinctive. Among them are features of the thigh bones related to upright posture and walking, canine teeth that are smaller and not sharpened against the lower teeth, thickly enameled teeth capable of resisting demanding foods, and a thumb capable of advanced precision handling. These fossils suggest that, at its earliest stages, the human lineage was set apart from our African ape ancestors by an increase in the importance of upright posture and walking as well as manual dexterity, possibly a shift in diet including harder or tougher foods, and a change in social strategy in which canine teeth were not used for social competition in the manner seen in other higher primates.

Otolith

Michael Khalil
University of Nicosia, Nicosia, Cyprus

Synonyms

[Otolithic membrane](#); [Otolithic organs](#)

Definition

Small calcium carbonate particles that compose the otolithic membrane.

Introduction

The otoliths are small calcium carbonate particles that make up the otolithic membrane, which accommodates the utricle and the saccule inside the vestibule (Chang and Khana 2013; Seikel et al.

2010). Their function contribute to balance and motion (Clarke et al. 2003).

The Sacculle

The otolithic membrane covers the utricular macula which is a sensory organ endowed of hair cells and cilia (Seikel et al. 2010). The sacculle has a globular-shaped sac which is located near the scala vestibuli in the vestibule (Lee et al. 2016). It is connected anteriorly to the cochlear duct by the ductus reuniens and posteriorly to the endolymphatic duct through the utriculosaccular duct (Lee et al. 2016). The sacculle is connected with the cochlea through the miniscule ductus reuniens (Seikel et al. 2010).

The Utricle

The utricle is larger than the sacculle, and is located posterosuperiorly to the sacculle in the elliptical recess of the medial wall of the vestibule. It is connected anteriorly through the utriculosaccular duct to the endolymphatic duct. The three semicircular canals are opened into it through five openings. The posterior and the superior semicircular canals have a single opening at the crus commune. The macula of the utricle lies in the horizontal plane and located in the utricular recess, which is the anterior part of the utricle (Lee et al. 2016).

Both the sacculle and utricle are connected through the endolymphatic duct, which is implanted in the dura mater. Since otoliths are denser than endolymph, gravitational forces help to deflect the stereocilia of the hair cells when the head is not moving (Hain and Helminsky 2007). The linear motion or the tilting of the head creates inertial drag and cropping force between the otolithic membrane and the macular surface, having as a result the bending of the hair cells (Oghalai and Brownell 2012) which helps to keep a person balanced while moving or staying constant. In other words, the sacculle senses up and down movement and the utricle

senses forward and backward movement, left and right movement, or a combination of the two (Lee et al. 2016).

Functions of the Otoliths

The functions of the otolith organs vary. Clarke et al. (2003) have listed in their study a list with citations of researchers who have studied the functions of the otoliths. Firstly, they state that the otolith signals have a vestibulo-ocular function. Specifically, there is an ocular counterrolling when the head tilts; a linear vestibulo-ocular reflex (to stabilize the images in the eyes while the head moves) during the translation of the otolithic signals; a dynamic ocular-counterrolling; inertial processing of vestibulo-ocular signals; vergence control during linear movements; and a modulation of velocity storage that leads to interaction between the semicircular canals and the otolith organs.

Secondly, the otolithic organs serve a vestibulo-spinal function. Specifically, they help to the maintenance of postural tonus, and there is a vestibulo-spinal readaptation after spaceflight (Clarke et al. 2003).

Thirdly, the otolithic organs serve a vestibulo-autonomic function. Specifically, they help with vestibular autonomic regulation, post-spaceflight orthostatic intolerance, and vestibular control of the sympathetic activity (Clarke et al. 2003).

Fourthly, the otoliths serve a gravitational function, where they help with oculogravic illusion and determination of subjective vertical and horizontal axis. They, also, serve to the perception of spatial orientation and the cognitive aspects of it (Clarke et al. 2003).

Conclusion

Otoliths are the small calcium carbonate particles that compose the otolithic membrane. They are known as the sacculle and utricle, and they serve a

variety of functions that help with balance and posture.

[Homophobic bullying](#)

Definition

The harmful effects that are caused by the victimization of sexual minorities.

Introduction

Lesbian, gay, bisexual, and transgendered (LGBT) individuals are often the victims of abuse because of their sexual orientation. Victims of homophobic abuse may suffer several negative psychological outcomes, including difficulty maintaining scholastic achievement, drug abuse, depression, and suicidal thoughts and behaviors (Birkett et al. 2009; Poteat et al. 2011). These negative effects stem from a wide array of consequences, including fear of physical abuse, social stigmatization and exclusion, decreased school attendance and performance, and negative attitudes toward peers and schools.

Outcomes of Homophobic Abuse

Research has shown that LGBT high school students experience high levels of harassment from their heterosexual peers, which leads to truancy levels that are significantly higher than average (Birkett et al. 2014). In fact, the Massachusetts Department of Education (2004) found that LGBT students are over four times more likely than heterosexual

students to skip school because they feel unsafe. One study found that 40% of LGBT high school students had problems with truancy because they feared abuse at school (Elias et al. 1992).

This decrease in school attendance leads to decreased academic performance. Studies have shown that 80% of LGBT students display a steady decline in academic performance compared to their heterosexual peers, and 30% of LGBT students drop out of school altogether (Elias et al. 1992). LGBT students are also more likely to have lower GPAs, as well as greater negative attitudes toward school, than their heterosexual peers (Russell et al. 2001).

Not only does homophobic bullying decrease school attendance, but it also increases feelings of social exclusion (Poteat et al. 2011). LGBT students who are bullied often feel different from their peers, alone, and ostracized. These feelings are correlated with drug abuse, depression, and suicidal ideation (Poteat et al. 2011).

Possibly as a means of coping with the stress produced by being the victim of homophobic abuse, LGBT adolescents who experience homophobic bullying are significantly more likely to abuse marijuana and alcohol (Birkett et al. 2009). This increased usage of marijuana and alcohol among LGBT adolescents has been consistently documented across more than 20 peer-reviewed studies (Birkett et al. 2009; Marshal et al. 2008; Poteat et al. 2011).

Increased rates of depression have also been consistently documented within the LGBT community (Poteat et al. 2011). One study found that 41% of young LGBT males and 28% of young LGBT females indicate troublingly high levels of depression (D'Augelli and Hershberger 1993). LGBT individuals also possess significantly higher rates of suicidal thoughts and behaviors than heterosexual individuals. For instance, one study found that 60% of LGBT individuals had contemplated suicide (Hershberger and D'Augelli 1995). This increased risk of suicide has been found to be heavily influenced by homophobic bullying (Birkett et al. 2009; Poteat et al. 2011).

Conclusion

Although homophobic bullying produces a wide array of harmful outcomes for LGBT individuals, these effects are strongly mitigated by a positive school climate. If schools have preventative measures in place to decrease or eliminate homophobic bullying, the negative outcomes significantly decrease (Russell et al. 2001). In fact, in positive and supportive school environments, LGBT individuals' rates of truancy, drug abuse, depression, and suicidal thoughts and behaviors were at the same low level as their heterosexual peers (Birkett et al. 2009). Thus, providing an environment of acceptance for LGBT students in schools would likely dramatically decrease homophobic bullying and significantly improve LGBT students' quality of life as well as their future.

External ear

Definition

The outer ear is responsible to capture sound in the environment.

Introduction

The outer parts of the ear are responsible for capturing sounds from the environment and transmitting them to the latter parts of the ear for further processing. The outer ear consists of the

pinna (auricle) and the ear canal (external auditory meatus).

The Pinna

The outer ear, otherwise called external ear, is consisted of the pinna, otherwise called the auricle (see Moller 2013; Seikel et al. 2010), the ear canal, otherwise called external auditory meatus, and the ear drum, which is the lateral portion of the tympanic membrane (Pickles 2012; Munir and Clarke 2013).

The pinna's main function is to collect sound to direct it to the area of the cochlea where the sound is further analyzed and processed. The pinna has many important functions, such as helping with the localization of sound in the environment (Seikel et al. 2010).

The Ear Canal

The sound arrives there through the ear canal (Seikel et al. 2010; Moller 2013). The ear canal has a length of roughly 2.5 cm and a diameter of roughly 0.6 cm, although its shape is enlarged over time – especially in men (Moller 2013). It is also covered by skin that secretes wax (cerumen) and has hairs on its surface. In the ear canal there are no sweat glands. There are two types of cells that help in the secretion of ear wax and are called sebaceous cells which are located close to the hair follicles and ceruminous glands. The wax has a minor antibacterial and antifungal function, and it can serve as an insect repellent (Moller 2013). However, if the wax is accumulated in the ear canal, it could lead to a hearing impairment, and if it covers the tympanic membrane, it could lead to a loss of hearing (Moller 2013).

Additionally, the outer layer of the skin (epidermis) in the ear canal together with the outer layer of the tympanic membrane migrates outwards, having as a result the healing of small injuries and the movement of cerumen. Failure of

this migration may cause inflammation of the ear canal (Moller 2013).

Furthermore, the skin of the ear canal is supplied with a variety of nerves. These are the sensory portion of the mandibular division of the trigeminal nerve, the facial nerve, the glossopharyngeal nerve, and the auricular branch of the vagus nerve which covers the posterior wall of the ear canal and the tympanic membrane (Moller 2013). These nerves explain why stimulation of the ear canal could affect heart rate, blood circulation, and fainting – especially in cases where the ear canal needed to be cleaned from wax (Moller 2013).

Furthermore, the ear drum forms a boundary between the outer and the middle ear, thus forming the beginning of the middle ear. The ear drum is divided into three bones called ossicles: the hammer, the anvil, and the stirrup (Balkany and Brown 2017).

Conclusion

The outer ear consists of the pinna, which serves as a sound collector, and the ear canal – or external auditory meatus. These structures contribute to capture the sound in the environment and transfer it to the deeper levels of the ear for processing.

University of Bristol, Bristol, UK

Synonyms

[In-group](#); [Intergroup conflict](#); [Out-group](#); [Prejudice](#); [Stigma](#)

Definition

A member from a group of people that have either been excluded or do not form part of your own group.

Introduction

Throughout a lifespan, any one individual will be affiliated to a number of different groups. Some groups are assigned at birth, such as belonging to a family. Some groups are selected by the individual, such as supporting a local football team. Recognizing and being affiliated to a particular group is known as being an in-group member. In contrast, those who are outside of this group, particularly those who may affiliate to a rival group, are referred to as out-group members. This entry will explore some of the explanations for why in-group/out-group categorizations are

formed, what the consequences are this for out-group members, and what factors can be deployed to minimize the consequences of out-group categorization.

Social Identity Theory

Tajfel and Turner's (1979) social identity theory proposed that people's social identity is based on the group memberships that they affiliate to. These group affiliations provide us with a sense of pride, a sense of belonging, and reinforces who we are as an individual. In order to increase our self-standing, members of particular groups, also known as in-groups, will promote the status and importance of their group. On a cultural level, this can lead to racism that is prevalent, both historically and in modern times. In addition to discriminating against out-groups, stereotyping can occur, whereby negative attributes are disproportionately associated with out-group members. Furthermore, members of an out-group can all be perceived as having these negative attributes, rather than them being applied on an individual-by-individual basis.

Tajfel and Turner (1979) identified three different stages that are required in order to create an in-group and out-group belief. The first is *social categorization*, allowing us to group different people into different categories. For example, people could be categorized on their gender, nationality, religion, or team that they support. It is therefore also clear that no one person will just belong to one category, but will belong to several. The second stage is *social identification*, when we identify with a group, act in a way that would be perceived by members of the group, and adopt their norms. For example, this could be wearing a replica jersey of a local sports team and singing their songs at local games. The third stage is *social comparison*. Once we have categorized people into groups and decided our group memberships, active comparisons are then made with other groups. In line with the social identity theory, this involves promotion of one's own groups and

being derogatory towards other groups in order to maintain and increase self-worth.

Out-Group Homogeneity Bias

The concept of not being able to differentiate characteristics of out-group members is known as out-group homogeneity bias (Anthony et al. 1992). Humans have limited attentional resources and cannot encode all information in a social world (Todd et al. 2005). These limited attentional resources are allocated to those objects or people who have functional implications to the perceiver (Ackerman et al. 2006). Historically, many interactions that took place in an in-group (also known as a coalitional group) would benefit an individual's functional outcomes. For example, interactions could facilitate potential mate selection and subsequent reproduction. Other interactions could facilitate opportunities for reciprocal exchange. For example, these could be economic exchanges, such as food and clothing, or they could be less tangible exchanges, such as social support. From a social standing, interactions could facilitate potential negotiations for movement in a social hierarchy. For example, being affiliated with a more prominent member of the group could increase your social status within a group. Increased technology and infrastructure has meant that coalitional groups changed significantly in modern times. Despite this, many of the interpersonal interactions identified still take place within cultural and ethnic groups (Fiske 1992). As a result, contact with out-group members tends to be less frequent, meaning that the costs of interpersonal contact outweigh the functional benefits.

Not being able to distinguish between out-group members is based on the notion that individuals can gain more from interactions with in-group members when compared to out-group members. However, this idea ignores situations when an out-group member may be a source of threat. In this instance, that out-group individual is likely to become more functionally relevant and

have even greater functional importance. In this instance, homogeneity bias toward out-group members is likely to be eliminated. The emotion and facial expression associated with recognizing interpersonal threat is anger. Ackerman et al. (2006) proposed that it is functional to be able to distinguish angry out-group members and remember them in order to avoid them in the future. In their study, 192 white participants were shown white and black faces with either a neutral or angry expression. Participants were then shown a 5 min distraction video and recognition memory task. Recognition accuracy for black faces was lower, supporting out-group homogeneity bias. However, this bias was eliminated for angry black faces. Furthermore, recognition bias for angry black faces was higher than angry white faces, supporting out-group heterogeneity. The functional explanation of these findings is that all out-group members are considered as being potentially dangerous, supporting out-group homogeneity bias. However, additional mechanisms allow the perceiver to identify those out-group members who pose the most threat, supporting out-group heterogeneity.

Perceived Threat

Due to the prevalence of intergroup violence throughout human history, it has been hypothesized that humans have evolved a set of tribal instincts that specifically deal with antagonist group situations (Van Vugt and Park 2010). These instincts are designed to divide up the world to “us” and “them,” favoring in-group members and acting hostile toward out-group members. However, not all in-group-out-group categories are the same. Van Vugt and Park (2010) proposed a “tribal template” that differentiated those out-groups who could pose a threat (e.g., nations, ethnic groups) from those who do not (e.g., age, gender). Moreover, the level of hostility toward out-group member is increased when contextual cues suggest increased threat (e.g., being in the dark).

In addition to the threat of potential physical conflict, there is also the more subtle type of threat associated with disease. In ancestral times, it was likely that contact with an in-group member posed less risk of disease threat when compared to out-group members. This was because constant contact with in-group members would have allowed the body to build up the appropriate antibodies as an immunological defense for in-group members but not out-group ones. Furthermore, in-group members were more likely to have the aid necessary to deal with illnesses that were common to them (Navarrete and Fessler 2006). This therefore suggests that humans have evolved an intergroup bias that is associated with approach and avoidance motivations. On the one hand, humans are predisposed to avoid those who are categorized as out-group members, as they pose a higher risk of disease threat. On the other hand, humans are predisposed to approach in-group members as they offer less risk of disease threat as well as offering knowledge and support for disease threats that are known within the group (Navarrete and Fessler 2006).

Contact Hypothesis

Out-group homogeneity bias and prejudice can be fuelled, in part, by lack of contact between different groups. Addressing this point, Allport's (1954) *contact hypothesis*, drew upon the idea that contact may reduce negative evaluation of out-group members, providing participants were of equal status, shared the same goals, have an opportunity to get to know each other, and have the support of an authority (e.g., a school or the government). Thus, increasing contact with an out-group member(s) serves as an opportunity to work towards a common goal and create individual-level commonalities. Furthermore, Pettigrew and Tropp (2008) conducted a meta-analysis to look at the psychological factors associated with contact. They found that out-group prejudice is reduced by reducing anxiety towards out-group members, increasing the knowledge

about out-groups, and increasing empathy towards out-group members. Despite this intuitive intervention, the question still remains as to whether contact does actually work on a global scale? While contact with outgroup members in this particular setting seems to work, does it mean a global shift in someone's ideological beliefs? Put more simply, would all out-group members be treated fairly in the future? (Dixon et al. 2005).

From an evolutionary perspective, the conditions stated by Allport (1954) would result there being little to distinguish between in-group and out-group members; and with consistent contact between all members, there would be no "us" and "them." This would create a melting pot and has the potential to eliminate discrimination, prejudice, and stereotyping. Despite this being ideologically perfect, it is also practically impossible. We are prone to categorizing, and this is done in a functionally flexible way. In other words, consistent contact may have the potential to create new in-groups (e.g., those that you have completed an activity with), but this will just create new out-groups in place of existing ones. Therefore, it is much more likely that interventions, such as education, can motivate understanding of out-group members, reduce social categorization and subsequent negative evaluation of out-group members.

Conclusion

Humans are a social species and are affiliated to a number of different groups, such as family, religion, ethnicity, and supporting a particular sports team, this is just part of human nature. Drawing from our understanding of limited attentional resources and functional explanations, we can understand both why we favor those from in-groups and why it can come at the expense of others. We also understand that this is not so black and white and can be influenced by other factors, such as perceived threat and increased contact. Furthermore, we all belong to several groups and it is likely that what we constitute as an out-group member will be based on how we weight and perceive our social identity on a multidimensional continuum.

Ovulation

Lisa L. M. Welling
Department of Psychology, Oakland University,
Rochester, MI, USA

Synonyms

[Conception](#); [Fertility](#); [Menstrual cycle](#); [Mid-cycle](#); [Ovulate](#)

Definition

In humans, ovulation occurs around mid-menstrual cycle when an oocyte is released from an ovary and sex can result in conception.

Introduction

Several scholars have suggested that human females have evolved to conceal ovulation from males (e.g., Marlowe 2004). However, other scholars contend that cues to ovulation have not been entirely hidden, but rather have only been partially concealed (see Welling and Puts 2014).

Although there is evidence in favor of both perspectives, there is considerable recent evidence in favor of the latter hypothesis. This research falls into four related areas of research: (1) cyclic variation in female mate preferences, (2) changes in female sexual motivation, (3) changes in female attractiveness, and (4) male detection of ovulation.

There is supporting evidence for the claim that women have evolved to conceal ovulation, such as inaccurate beliefs surrounding the timing of conception among hunter-gatherers (Marlowe 2004). Ovulation may have been concealed for more than one purpose; concealed ovulation may have prevented women from selectively avoiding sex at certain times to avoid conception (Burley 1979), allowed women to better deceive their partners (e.g., Strassmann 1981), or enabled greater flexibility in choosing a mate (e.g., through cuckoldry; see Strassmann 1981). Similarly, the extended mating periods of humans coupled with concealment of cues to fertility may have evolved to make assessment of paternity more difficult, which may reduce rates of male-perpetrated infanticide if they are less likely to deduce nonpaternity (e.g., Heistermann et al. 2001). Certainly, degree of relatedness is related to violence toward children (Daly and Wilson 1985; Wilson and Daly 2002), suggesting that knowledge of nonpaternity could have severe negative impacts on children. Alternatively, concealed ovulation may have evolved to protect women from sexual attention from unwanted suitors when that attention could prove particularly devastating (i.e., result in unwanted pregnancy; discussed in Welling and Puts 2014).

Increasing research on physical and behavioral cues to women's fertility status has surfaced in recent years (e.g., Gildersleeve et al. 2014). Recent evidence suggests that cues to fertility status have not been entirely hidden, but rather have merely been partially concealed (Welling and Puts 2014). Evidence in favor of this hypothesis comes from four areas of research: (1) cyclic variation in female mate preferences, (2) changes in female sexual motivation, (3) changes in female attractiveness, and (4) male detection of ovulation. These subtle signs of conception risk

indicate that the previously accepted conclusion that ovulation is concealed in humans is not the whole story. Each of these areas is discussed in turn below.

Cyclic Variation in Female Mate Preferences

A variety of women's behaviors change as a function of menstrual cycle phase, such as increased creativity (e.g., Krug et al. 1996) and performance on cognitive tasks (e.g., Becker et al. 1982) near ovulation relative to other times. Importantly, these findings introduce the possibility that hormonal variation could have implications for women's mating-relevant behaviors. The ovulatory shift hypothesis states that systematic changes in female mating-related behavior and preferences should be expected over the course of the menstrual cycle (e.g., Gildersleeve et al. 2014). Should, for example, women's preferences shift toward cues to genetic immunocompetence, this would be quite adaptive because those women would reap the indirect genetic benefits whereby their offspring would be more likely to survive into adulthood and propagate their genetic line. Consistent with this view and in line with the ovulatory shift hypothesis, several studies report increases in women's preferences for putative cues to male mate quality, including preferences for the odor of men who are more dominant, symmetrical, and genetically compatible (e.g., Havlíček et al. 2005). Women also show increased preferences for masculine male faces, masculine male body shape, masculine vocal characteristics in men's voices, and facial symmetry around ovulation relative to other times in the menstrual cycle (reviewed in Welling and Puts 2014). It is likely that women's shifts in preferences across the menstrual cycle are driven by hormonal changes, although there is debate surrounding whether menstrual cycle preference shifts are driven by estradiol, progesterone, testosterone, cortisol, or some hormonal combination (reviewed in Welling and Puts 2014).

Other mate-choice relevant shifts occur across a woman's menstrual cycle. Preferences for male

dominant and competitive behavioral displays (e.g., Gangestad et al. 2004) and for courtship language (Rosen and López 2009) are highest near ovulation. When judging the attractiveness of video clips of men competing for a lunch date for a short-term (i.e., sexual) relationship, women rate men who display social presence and direct intrasexual competitiveness as more attractive on high- versus low-fertility days (Gangestad et al. 2004). Furthermore, women are more receptive to courtship in the late-follicular phase of the menstrual cycle (the fertile phase immediately preceding ovulation) compared to the luteal phase (the nonfertile phase following ovulation; e.g., Guéguen 2009). Women are even more accurate when classifying faces as male near ovulation (Macrae et al. 2002), especially when those faces are more masculine (Johnston et al. 2008). Interestingly, this finding is reversed among lesbian women, who categorize female faces more accurately around ovulation (Brinsmead-Stockham et al. 2008), suggesting that these findings are mate-choice specific.

Changes in Female Sexual Motivation

High conception risk is associated with increases in sexual desire, sexual fantasy, attention to attractive men, sexual self-stimulation, arousal in response to sexually explicit material, sexual activities, and desire for orgasm near ovulation (reviewed in Welling and Puts 2014). Sexual encounters increase (Wilcox et al. 2004) and are more likely to be female-initiated (e.g., Matteo and Rissman 1984) near ovulation. Women are more disgusted by incest around mid-cycle (Fessler and Navarrete 2003) and may decrease their risk-taking behaviors near ovulation (e.g., Bröder and Hohmann 2003). This latter finding may function to decrease chances of victimization, although sexual assault is no less frequent during high fertility (Fessler 2003). Thus, evidence suggests that sexual motivation increases with conception risk, whereas nonadaptive mating behaviors may simultaneously decrease.

Women are more sexually opportunistic (Gangestad et al. 2010), are less motivated toward sex for the purposes of intimacy (Sheldon et al. 2006), and are more interested in visiting singles nightclubs without their romantic partner (Grammer et al. 1997) near ovulation. They also demonstrate a greater interest in attending social gatherings, extra-pair men, extra-pair sexual activity, and extra-pair sexual fantasies when conception is more likely (reviewed in Welling and Puts 2014). Fertile-phase women report less commitment to, and relationship satisfaction with, their current partner. Perhaps as a consequence of an increase in mating motivation, female intrasexual competition increases near ovulation; women derogate same-sex competitors by downplaying their physical attractiveness (e.g., Fisher 2004), which effectively reduces men's attraction to their rivals (Fisher and Cox 2009). Women also report feeling more attractive (reviewed in Welling and Puts 2014) and are more willing to spend money on suggestive clothing (Hill and Durante 2009) around ovulation than at other times. Altogether, this research suggests that women are more mating motivated when they are more likely to conceive.

Changes in Female Attractiveness

Women modulate their appearance and clothing to enhance their attractiveness when they are most fertile, possibly as a reaction to a peri-ovulatory decrease in self-esteem (Hill and Durante 2009). Also, their faces, voices, and bodies are rated as more attractive around ovulation than at other times (reviewed in Welling and Puts 2014). Women have a more appealing body odor around ovulation (e.g., Miller and Maner 2010). Exotic dancers even receive more tips during peak fertility versus other points in the menstrual cycle (Miller et al. 2007). These studies suggest that men are maximally attracted to ovulating women and, by extension, that women are better able to attract men during the fertile phase of their cycles.

Male Detection of Ovulation

Given that attractive women receive more male attention (Buss and Barnes 1986) and that appear to be more attractive and sexually motivated around mid-cycle, increased attention from long-term partners would be expected near ovulation. Indeed, three studies have shown a relationship between female conception risk and their perceptions of jealous and possessive behaviors from their male partners (Gangestad et al. 2002; Haselton and Gangestad 2006; Pillsworth and Haselton 2006), and this relationship is strongest when the woman is particularly attractive (Haselton and Gangestad 2006) or interested in extra-pair mating (Gangestad et al. 2002). Similarly, women with less sexually attractive partners report receiving more attention from their partners around ovulation (Pillsworth and Haselton 2006). Overall, these findings suggest either that women's attention to extra-pair men may drive this increased attention or that men are sensitive to fertility-associated cues and become more responsive to the threat of cuckoldry.

There is evidence that women's ovulatory status influences male hormonal response. In a double-blind study, Miller and Maner (2010) investigated how the scents of women at peak fertility influence male endocrinological responses by having men smell T-shirts worn by women near ovulation or T-shirts worn by the same women during the luteal phase of the menstrual cycle. When controlling for baseline testosterone levels, testosterone was substantially higher in men exposed to the odor of a woman close to ovulation than in men exposed to the odor of a luteal-phase woman (Miller and Maner 2010). Additional research has shown that partnered men exposed to high-competitive rivals demonstrate significantly higher testosterone levels at high-relative to low-fertility, whereas men exposed to low-competitive rivals showed no such pattern (Fales et al. 2014). Moreover, men are also more likely to mimic a woman (a behavior thought to reflect attraction) and make risky decisions (a decision-making strategy men use to display desirable traits to women) when faced with a fertile-phase woman versus women in nonfertile

menstrual cycle phases (Miller and Maner 2011). Thus, men not only perceive cues to female conception risk but these cues may have a direct influence on their hormonal profile and their behavior.

Conclusion

That attractiveness and sexually motivated behavior appear to increase at ovulation contradicts the supposition that human ovulation is completely concealed (discussed in Welling and Puts 2014). These cues to fertility are quite subtle, however, possibly to avoid indiscriminate attention that may constrain or eliminate female choice. Although cues to ovulation and associated changes in male and female behavior and preferences are becoming increasingly well documented, additional research is needed to further tease apart the many complex mechanisms underlying human sexual selection.

Definition

Hormones that induce ovulation and regulate the ovulatory cycle.

Introduction

The key to the ovulatory cycle resides within the ovaries, and the primary hormone that regulates the ovulatory cycle is Estradiol. Every month, a follicle (egg) is randomly selected to release from the ovary. The first day of menstruation marks the beginning of the ovulatory cycle, and the start of the follicular phase. During the first 3–5 days of menstruation, Follicle-stimulating hormone (FSH) is triggering the growth of immature ovarian follicles. Estrogen is steadily increasing during this time; aiding in follicle development, thickening the endometrial lining in the uterus and in a general sense, promoting sociosexuality (Gray and Garcia 2013). A few days before the end of the follicular phase, estrogen surges as luteinizing hormone begins to rise, ultimately peaking when the follicle is released at the point of ovulation. When the follicle is released from the ovary, a lipid-rich substance referred to as the *corpus luteum* remains behind and stays active, steadily increasing the presence of progesterone (Gray

and Garcia 2013). The ovulatory cycle is then considered to be in the luteal phase and is characterized by the rising presence of progesterone. Progesterone continues to stimulate the endometrial lining in the uterus and prepare it for the potential arrival of a fertilized egg for the remainder of the luteal phase. If conception does not occur, the built-up uterine lining is shed and menstruation begins, marking the beginning of a new ovulatory cycle.

There are also changes in women's body odors that coincide with the hormones of her ovulatory cycle. Researchers asked women to wear a t-shirt to bed on various days throughout their cycle while avoiding practices that would mute their natural scent (no perfume, deodorant, etc.). Men were then asked to smell and rate numerous t-shirts for odor attractiveness. T-shirts that were worn when women were in their peak ovulatory phase were typically rated as smelling more attractive than t-shirts that were worn during the other phases of the cycle (Singh and Bronstad 2001). This was coined the "stinky T-shirt" paradigm. Kuukasjarvi et al. (2004) took this idea and added the extremely important mediating factor of oral contraceptives. Oral contraceptives (and really, any type of hormonal contraceptive) basically trick the female body into thinking that it is pregnant throughout the month, therefore never producing a peak in ovulatory hormones mid-cycle. When individuals were presented with various t-shirts to smell from various women in different phases of their ovulatory cycle, the same effect was found regarding ovulating women. What is fascinating is that there was no effect for women that were on the pill, supporting the idea that women's body odors are linked to the ebb and flow of hormones throughout the ovulatory cycle. Body odors oscillate slightly depending on where an individual is in their cycle *unless* they are on some sort of hormonal contraceptive.

Some researchers have proposed that, similar to other animals, humans possess pheromones. Pheromones are basically unseen chemical cues that our bodies use to interact with the physiology and behavior of others in our immediate environment. In particular, it is hypothesized

that two pheromones are typically released by women throughout their ovulatory cycle: a phase-advance and a phase-delay pheromone. Stern and McClintock (1998) demonstrated that when compounds from the armpits of women in the late follicular phase of their menstrual cycle were introduced to recipient women, it triggered a surge of luteinizing hormone and shortened their cycles. When the compounds from the armpits of the same women were collected at ovulation and introduced to recipient women, an opposite effect was found: luteinizing-hormone was delayed and menstrual cycles were lengthened.

Miller et al. (2007) found that (over the course of 3 months) women (exotic dancers) that were normally cycling (and were not on any type of hormonal contraceptive) received more money on average when they were ovulating. During a 5-h shift, ovulating women on average earned \$335, in comparison to an average of \$260 when they were in their luteal phase and \$185 when they were menstruating. So women who were normally cycling made the most money when they were in estrus (ovulating) compared to all other phases of the cycle – especially the women who were on hormonal contraceptives. Because hormonal contraceptives make it so that there is no peak in hormones (or fertility for that matter), the dancers that were on birth control made less on average (\$193 per shift vs. \$276 per shift). Due to these results, researchers claimed that unconscious cues were being shared to indicate where a female was in her ovulatory cycle.

Conclusion

Ovulatory hormones regulate much of the fluctuations within the female body, and they effect more than the subtle cyclic changes that happen throughout the month. As humans, we have come up with novel ways to manipulate the ovulatory cycle in order to avoid unwanted pregnancies, and in doing so, we have manipulated the subtle behavioral changes that have historically accompanied the cycle.

Definition

Hormones that induce ovulation and the changes incurred in human behavior.

Introduction

Though the human ovulatory cycle is incredibly complex, it should come as no surprise that it shares striking similarities to other apes. The exact length varies depending on the individual, but the average ovulatory cycle lasts about 28 days. During the length of a cycle, a female goes through three distinct phases: menses, follicular, and luteal. Ovulation typically occurs halfway through the cycle, between the follicular and luteal phases (with the length of the follicular phase being the more variable of the two). The term *peak fertility* refers to a small window (usually thought to be anywhere between 2 and 6 days) when a female's conception rate goes up. In some species (including some distant ancestors like baboons), *sexual swelling* is a visual indicator that a female is approaching and/or in her peak fertility window (Gray and Garcia 2013). This visual cue is necessary to facilitate copulation, which in turn leads to reproduction, an essential outcome for evolutionary mechanisms to work.

Concealed Ovulation?

Humans obviously do not display this clear indicator when nearing ovulation, and therefore are considered to display *concealed* or *cryptic ovulation*. For millions of years, various evolutionary mechanisms shaped the ovulatory cycles of our distant ancestors, but as *homo sapiens* emerged as a distinct branch of great apes and became more specialized, so too did the behavior that evolved surrounding our ovulatory cycles. Though humans are thought to have *concealed ovulation*, females display (subtle) physiological, psychological, and behavioral indications when in their peak fertility phase. These behavioral adjustments, shaped by various evolutionary forces (like sexual selection), bolstered an individual's ability to conceive, and ultimately led to successful reproduction. Throughout each generation, the behaviors that increased an individual's ability to successfully reproduce were selected for, ultimately becoming indicators of reproductive fitness.

Attraction to an individual can also be affected by the ovulatory cycle. Physically, there are small adjustments to a female's appearance when she is nearing her peak fertility phase due to hormones. Soft tissue traits (ears, fingers, breasts) become more symmetrical; lips become fuller, and have a slightly deeper hue, and even the tone of a female's voice changes. Pipitone and Gallup (2008) demonstrated that women's voice attractiveness varies across the ovulatory cycle. The human larynx is (not surprisingly) affected by the hormones of the ovulatory cycle. When students were asked to rate how attractive a speaker's voice was, the highest ratings came from women that had the highest risk of conception probability. That is, when women were closer to ovulation, their voices were rated as more attractive than women that were at different phases in their cycle (Pipitone and Gallup 2008). From an evolutionary perspective, if a females' voice is perceived as more attractive during her peak fertility days, and increased attraction can lead to an increased potential for copulation, this can play out in terms of reproductive fitness.

Sexual Desire

Another important factor to consider when discussing peak fertility and conception probability is sexual desire. Sexual desire is an emotion that most likely evolved to coordinate a multitude of psychological mechanisms, ultimately working together to direct behavior toward increasing the odds of reproduction. Environmental cues play an important part in women's evolved psychology. For example, relationship satisfaction is extremely important when considering the effect of the ovulatory cycle on sexual desire: Women are more likely to feel increased sexual desire during peak fertility days for their partners if they are in happy, committed relationships. Interestingly, sexual desire for extra-pair copulations during peak fertility is positively correlated to the length of relationship (Pillsworth et al. 2004). This overall increase in desire in mated couples is compelling: The happier the couple is, the more likely the woman is to feel sexual desire (during her peak ovulatory days), but, as the length of the

relationship increases, the more likely she is to experience sexual desire for extra pair copulations during ovulation.

Attractiveness and Desire

Interestingly, partner attractiveness can moderate the psychological effects of the ovulatory cycle. When females rate their male partners as less sexually attractive, there is a significant shift at ovulation toward extra-pair sexual desire. A considerable portion of attraction lies in symmetrical features of the face. Fluctuating asymmetry moderates the effects of in-pair and extra-pair attraction in both directions: women with less symmetrical partners experience heightened extra-pair sexual desire when ovulating, and women with more symmetrical partners experience heightened in-pair sexual desire (Pillsworth and Haselton 2006). The degree to which a female's partner exhibits traits that are indicative of *high-fitness genes* is thought to be what drives this ovulatory shift in desire. Subtle genetic cues are essentially motivating a females' drive toward desire.

Indicators of *high-fitness genes* can be expressed *phenotypically*. Our *genotype* is the set of inherited instructions we receive from both parents that code for a multitude of attributes, including physical appearance. The physical manifestation of our genetic code (or, genotype) is referred to as *phenotype*. Specific phenotypic traits are thought to be linked to high indices of genetic fitness. In women, these traits include smooth skin, large eyes, full lips, and curved hips; in men, these traits include broad shoulders, strong jawlines, moderate muscles, and tallness. As mentioned earlier, when a female is in her peak ovulatory phase, the aforementioned phenotypic attributes become slightly more enhanced. So too, does the desire for specific phenotypic fitness indicators.

Dual Mating

The evolutionary push to find a good partner often creates friction. Sometimes, individuals are

presented with a weigh off: do they choose the individual that they are highly sexually attracted to, but doubt their fidelity and sincerity, or the individual that would be a good partner and has always been there for them, but, they are not as attractive as the other. . . When it comes down to it, most people would say the good partner, but when females are ovulating, this shift toward sexual attraction (and potentially "genes") is stressed slightly more. *Dual mating* is a strategy in which a female has a long-term committed partner, but unintentionally seeks out "good genes" through extra pair copulations.

Dressing During the Ovulatory Cycle

The ovulatory cycle can also affect the way in which a female chooses to dress. From an evolutionary perspective (under some circumstances), clothing choice may be evaluated as a courtship signal. Haselton et al. (2007) found that near ovulation, women's choice in dress became more provocative. Participants were brought in on a low fertility day and a high fertility day during the month, and their pictures were taken. When in their peak fertility days, women were more likely to wear skirts, wear more fashionable clothing, and show more skin on their upper body. In a similar study, participants were additionally asked to illustrate what they would wear to a social outing (during high fertility days), their illustrations showed more skin. In particular, this trend was strongest for women that were sexually unrestricted, meaning that single women were more likely to draw revealing clothing during their peak fertility days than women who were in committed relationships (Durante et al. 2008). Both of these studies seem to fit nicely into the idea that an increase in sexual desire was only found to peak in mated couples. Women who were in committed relationships experienced a peak in sexual desire during their peak fertility days, yet did not show a difference in dress choice, whereas single women did not experience a peak in sexual desire, and tended to dress in more revealing clothing at the onset of ovulation. Extending beyond that idea, a silhouette of women's body movements (specifically gaits and

dances) were recorded in the late follicular and mid-luteal phases of the cycle (Fink et al. 2012). Body movements during the late follicular phase of the cycle were considered more attractive than the mid-luteal, further supporting the idea that there are not only changes throughout the ovulatory cycle, but that individuals have a potential ability to detect subtle ovulatory cues.

Preferences for Partners

The ovulatory cycle can affect an individual's preference as well. Haselton and Miller (2006) found that when a woman was looking for a short-term partner and was in her peak fertility window, she tended to favor creativity (potentially high genetic fitness) over wealth (financial stability). This is based off of the general idea that human female sexuality is adaptively sensitive to trade-offs between “good genes” and “good dads.” In a general sense, *creative intelligence* is something that would be a valuable trait to pass on to future offspring. These evolutionary trade-offs seem to increase around ovulation: In general, women want a partner who will care for them, be trustworthy and offer financial stability, yet they also want an individual they are mentally and physically attracted to.

The level of estrogen in a woman's system seems to have a direct effect on preferences toward dominant personality traits. When searching for long-term mates, preferences for dominant personality traits seemed to positively correlate with levels of estrogen (which fluctuate throughout the cycle), but when searching for a short-term mate, these same preferences toward dominance seemed to positively correlate with luteinizing hormone and follicle-stimulating hormone (which peaks 1–3 days after ovulation). There is no peak in preference for dominant personality traits when a woman is rating a long-term mate, but, when rating a short-term mate, a preference for dominant personality traits began rising as the day of ovulation got closer, finally peaking 1–2 days after ovulation (Lukaszewski and Roney 2009). From an evolutionary point of view, this makes sense because the preference for

dominant personality traits steadily increases while a female approaches her peak fertility days, and if she is looking for a short-term mate (or extra pair copulation for that matter), she will be more likely to pursue a sexual encounter during this time.

Certain behaviors, like mate guarding, have evolved as a countermeasure in the evolutionary arms race. From an evolutionary standpoint, behaviors that will increase the likelihood of a partner spending time with you during peak fertility will increase the odds of conception. Interestingly, this seems to be moderated by indicators of genetic fitness: We only see an increase in mate guarding behavior during peak fertility days when female physical attractiveness is rated relatively low. When female physical attractiveness is rated as relatively high, mate guarding takes place throughout the cycle (Haselton and Gangestad 2006).

Conclusion

There are many factors that can affect a females' psychology, including the ovulatory cycle. The hormones that are responsible for regulating the inner-workings of the cycle can also play into the psychology of that individual. Though it is important to consider the ovulatory cycle when studying ovulatory shifts in psychology, it is equally important to understand the complex interplay that the ovulatory cycle has with an individual's immediate environment. This immediate environment includes potential partners and partners (including their relationship satisfaction).

Oxidants

Definition

The outcome of disbalance between oxidants and antioxidants is known as oxidative stress (OS).

Introduction

Oxidation of substrates occurs during the process of aerobic metabolism, a crucial step towards efficient production of energy in the cells. There occurs a steady state balance between oxidation-reduction processes within the cell. During the process of substrate oxidation, free radicals particularly reactive oxygen agents with known toxicity are produced in low levels. Usually these free radicals are soon cleared by several antioxidant mechanisms preventing their accumulation. Oxidative stress is defined as “an imbalance between oxidants and antioxidants in favour of oxidants, potentially leading to damage” (Sies 2000). Various pathologic process disrupt this balance leading to oxidative stress which can occur both through the failure of the antioxidant mechanisms as well as the excessive production of prooxidants in the body (Kar and Choudhury 2016; Sies 2000).

Oxidative Stress

Oxidative stress is responsible for the generation of several reactive oxygen groups which are commonly referred as reactive oxygen species (ROS) too. In general, the molecular oxygen taken up by cells gets reduced to water by electron-transport mechanism during aerobic metabolism of substrates in mitochondria. Impairments of electron-transport mechanism in the respiratory chain lead to generation of partially reduced ROS. Apart from this, several intracellular enzymes such as xanthine oxidase, NADPH oxidase, cytochrome P450 monooxygenase, lipoxygenase, cyclooxygenase, and monoamine oxidase also play role in the production of ROS (Lee et al. 2013). The ROSs include superoxide, hydroxyl, hydrogen peroxide, and monovalent oxygen ion (Pizzino et al. 2017). They have roles in modulating

various cellular physiological processes (such as signalling, protein phosphorylation, activation of transcription factors, cellular differentiation, immunity, and apoptosis) (Pizzino et al. 2017; Rajendran et al. 2014).

Free Radicals

The free radicals are highly reactive moieties with unpaired electron that readily alter the structure and functioning of nucleic acids, proteins, carbohydrates, and lipids of the cell leading to injury and cell death (Ng et al. 2008). They have the potential to trigger apoptosis as well as necrosis. The major free radicals either belong to the reactive oxygen or nitrogen class of agents (e.g., hydroxyl radical, superoxide radical, peroxynitrite radical, and nitric oxide radical). Among these free radicals, hydroxyl radical is the most reactive. It rapidly reacts nonselectively with various compounds. In low to moderate concentrations, the free radicals deliver many physiological functions as well as provide immunity against infections (Valko et al. 2007). They are enzymatically produced as a by-product during cellular respiration, in activated leukocytes during inflammation, during metabolism of exogenous chemicals or drugs, as well as intracellular reaction involving transition metals like iron and copper (e.g., Fenton reaction). Ionizing radiations (e.g., ultraviolet light, x-rays) can nonenzymatically produce free radicals. Free radicals can be produced from endogenous or exogenous sources (Pizzino et al. 2017). Figure 1 enumerates the sources of free radicals.

Free radicals being highly reactive and unstable perish spontaneously. Body's natural antioxidant system attempts to neutralize the reactive oxygen agents. Several enzymes (such as superoxide dismutase, catalase, glutathione peroxidase, glutathione reductase, sulfiredoxin) and free radical scavenging molecules (such as vitamin E [tocopherols], vitamin C [ascorbic acid], vitamin A [retinol], polyphenols, flavonoids, glutathione, and uric acid) form the antioxidant reserve of the body (Pandya et al. 2013).

Mechanism of Action of Free Radicals

The free radicals target the lipids within plasma and organellar membranes, and produce damage to them by causing peroxidation. Peroxides formed this way used to be unstable and reactive and thus stems a chain of autocatalytic reaction leading to accumulation of oxidants. This results in widespread damage to organelles and cell membrane.

They also lead to alterations in protein structures by oxidizing amino acids, formation of covalent bonds (e.g., disulfide bonds) between proteins, and damaging the protein backbone. Oxidative damage to the proteins results in the alteration of enzyme binding sites, structural alteration of the proteins (receptors, transcription factors, and enzymes, etc.), as well as their proteosomal degradation.

Free radicals may target nitrogen-containing nucleobases or sugar residue leading to cross-linking of DNA strands, breaks in DNA strands, and formation of adducts. It thus damages cellular DNA.

Health Implications of Oxidative Stress and Free Radicals

During illness conditions, excessive unregulated production of oxidants occurs. The scavenging system (enzymes and nonenzymatic agents) fails to control the oxidants resulting in continuous tissue damage (Sies 1997). The oxidative stress and free radicals has been implicated in various illnesses like – inflammatory disorders, infections, diabetes mellitus, atherosclerosis, hypertension, cancer, metabolic disorders, and many other life style-related illnesses (Pizzino et al. 2017; Sies 2015). The inflammatory changes in atherosclerosis are due to increased formation of ROS. The ROS also damages the vascular endothelium (Kattoor et al. 2017). Medications like – statins, aspirin, angiotensin converting enzyme inhibitors reduce oxidative stress by their antioxidative effect (Kattoor et al. 2017). Oxidative stress produces epigenetic instability by damaging the DNA (e.g., producing oxidation and methylation

Sources of free radicals

Oxidative Stress and Free Radicals, Fig. 1 Endogenous and exogenous sources of free radicals

of DNA), which might lead to development of cancer (Nishida et al. 2013; Pizzino et al. 2017).

The brain is an organ with high energy demand and is reliant on aerobic respiration for efficient ATP production. It utilizes about 20% of total blood oxygen and is thus associated with an elevated risk of generation of free radicals and oxidative injury. Insufficient antioxidant defense mechanisms and high lipid content makes it further vulnerable. In addition, insufficient regenerative capabilities of neurons except for some stem-cell regions leave it susceptible to oxidative stress. Growing body of evidence has demonstrated disturbances of antioxidant defense mechanisms and increased oxidative stress in various neuropsychiatric disorders, including schizophrenia, bipolar disorder, autism depression, obsessive compulsive disorder (OCD), and anxiety disorders (Kar and Choudhury 2016). Oxidative

damage has also been a well-recognized phenomenon in the pathophysiology of various neurodegenerative disorders (e.g., Alzheimer's disease (AD), Parkinson's disease (PD), amyotrophic lateral sclerosis, and Huntington disease) (Niedzielska et al. 2016).

In Alzheimer's disease, there occurs increased production and accumulation of amyloid β and neurofibrillary tangles in the brain, which results in extensive oxidative damage. Oxidative damage has also been reported in PD. Significant lipid peroxidation in substantia nigra has been demonstrated. Oxidative protein damage was suggested to occur late during PD progression. Elevated markers of oxidative damage of DNA and RNA in brain has also been reported (Niedzielska et al. 2016).

In schizophrenia, various studies have reported oxidative stress; however, the results have been

variable with regard to the role of antioxidant enzymes with both reduced and elevated levels of superoxide dismutase (SOD) reported in an affected population. A meta-analysis evaluating the risk of oxidative stress in schizophrenia demonstrated that SOD activity was significantly decreased in the disorganized type of schizophrenia patients compared to healthy controls (Zhang et al. 2010). However, some recent studies also demonstrated increase or no significant difference in SOD levels and suggested the rise in levels as a compensatory response to oxidative stress. Oxidative stress markers upsurge may not be significant in the patients with first-episode psychosis (FEP). However, greater inflammation and oxidative stress indicate poor prognosis in this population (Fraguas et al. 2017). Oxidative stress parameters have also been suggested as the indicator of clinical status. The total antioxidant status, RBC catalase, and plasma nitrite are considered as the state markers for acute exacerbations of psychosis, whereas RBC superoxide dismutase to be a trait marker for schizophrenia (Flatow et al. 2013).

Patients with bipolar disorder exhibit significantly more lipid peroxidation, DNA/RNA damage, and nitric oxide compared to healthy controls. Lipid peroxidation was found consistently in both serum and postmortem brain samples and has been suggested as potential prognostic biomarker of bipolar disorder (Brown et al. 2014).

Major depression is associated with reduced plasma levels of antioxidants (uric acid, albumin, high-density lipoprotein cholesterol, vitamin E, zinc, and coenzyme Q10) and lower level of antioxidant enzymatic (serum paraoxonase and glutathione peroxidase) activity (Liu et al. 2015; Maes et al. 2011). Products of oxidative damage (such as red blood cell and serum malondialdehyde and 8-F₂-isoprostanes, 8-Hydroxy-2'-deoxyguanosine) are higher in depressed patients (Liu et al. 2015).

Evidences support that higher level of oxidative stress present in patients with OCD as well as their blood relatives who were healthy. This finding indicates to the possibility of oxidative

stress parameters as trait markers (Shrivastava et al. 2017).

Several pharmacological and non-pharmacological interventions have been shown to reduce oxidative stress. Antidepressant therapy was shown to enhance the levels of several antioxidant markers of oxidative stress (OS) in patients with depression (Liu et al. 2015). Drug treatment in bipolar patients also partly reduces the oxidative stress (Brown et al. 2014). Exercise during acute phase increases ROS production. However, in due course, antioxidant response compensates for this taking precedence. Exercise training regardless of the intensity, volume, type, and population tend to increase the antioxidant indicators and decrease prooxidants (de Sousa et al. 2017).

Conclusion

Oxidative stress and free radicals are important in a spectrum of health conditions. Life style modifications and appropriate therapeutic interventions can alter production of oxidative stress and free radical production to a greater extent. Preventing oxidative stress and generation of free radicals can prevent many neuropsychiatric disorders and life style-related disorders.

Definition

Pair bonding addresses the role and function of the attachment system for long-term mating relationships. The attachment system is thought to have been co-opted by evolution to foster pair bonds because such bonds increased reproductive fitness for both infants and mates. Attachment-related variations are also thought to influence mating behavior and people's stance towards pair bonds.

Introduction

Attachment theory, as formulated by John Bowlby, seeks to explain how the human species has solved one main obstacle to reproductive fitness in the course of evolution – how to survive the dangers of infancy. Universally, human infants form strong affectional bonds – attachments – to their caregivers; seeking to maintain proximity to and protesting separations from their caregivers, using them as a secure base to explore the environment from, and a safe haven to return to for comfort and protection. According to Bowlby, the tendency to form such bonds evolved in response to the child's innate vulnerability. This is because a behavioral system functioning to secure proximity to caregivers would have implied increased chances of protection, which in turn increased chances of survival and reproduction, in the primeval environments most formative for our species' development (i.e., the environment of evolutionary adaptedness, EEA; see ► [“Infant Survival”](#)).

Bowlby also asserted that the attachment system is integral to human functioning throughout the life span (Bowlby 1969). This claim has been supported by a large body of evidence. For instance, child-caregiver and pair-bond relationships display unique phenomenological, behavioral, functional, neural, and endocrine similarities, indicating that the attachment system is operative in both kinds of relationships. Individuals' stance towards pair bonds (i.e., romantic attachment styles) has also been robustly linked to numerous aspects of relationship functioning (see ► [“Attachment in Adulthood”](#)).

However, while the adaptive benefits of attachment bonds in childhood are hard to dispute, the evolutionary functions of pair bonds are not as self-evident. This entry addresses the role of the attachment system in the evolution of pair bonding, and the evolutionary functions of such bonds. Moreover, in the course of development, the attachment system is thought to become integrated with the caregiving and sexual mating systems, making variations in adult attachment more complicated to interpret. Indeed, different views on the nature of such variations, as well as on the relative importance of these three systems for pair-bond functioning, have sparked a

controversy among researchers. The entry closes with a discussion of this controversy.

The Evolutionary Function of Pair-Bond Attachment

Increased Offspring Survival by Means of Strong Affectional Ties between Mates

Although exceptions exist both across and within cultures, human reproduction typically takes place within long-term pair bonds (Mellen 1981). This trend is thought to have followed a birthing crisis due to two opposing evolutionary pressures in our primeval environments. As humans developed bipedal locomotion, they also developed larger heads, housing more developed brains. This made it harder for infants to pass through the birth canal of our female ancestors. The pressure for bipedal locomotion, however, restricted the development of larger birth canals to accommodate this trend (i.e., the obstetrical dilemma). Prematurely born infants, with less developed brains and smaller and more flexible skulls, were then more likely to survive (Rosenberg and Trevathan 1995).

Decreased infant maturity at birth also resulted in a prolonged period of heightened neural plasticity. This may have been evolutionarily advantageous because it enabled behavioral systems that are not rigid but open for learning based on experience (cf. experience expectant and experience dependent learning; see also ► [“Evolutionary Foundations of the Attachment System and its Functions”](#)). The relative benefits of premature birth were, however, also accompanied by a protracted period of infant vulnerability. More extensive co-operative efforts by parents may therefore have increased children's chances of surviving this period.

According to attachment theorists Zeifman and Hazan (2016), the evolutionary function of adult attachment is likely to be found in this context. In a situation where increased joint parental investment in infants would be adaptive, the human species already possessed a highly specialized behavioral system for ensuring that an individual would be motivated to stay close to another and resist separations – the attachment system. Albeit

originally developed to ensure protection of infants, the attachment system may then have been co-opted by evolution (i.e., through exaptation) to foster strong affectional ties between mates, increasing the likelihood of cooperative parenting efforts (Zeifman and Hazan 2016).

Supporting this notion, a number of unique aspects of human sexuality seem to have evolved with the function of facilitating enduring ties between reproductive partners, rather than of genetic reproduction alone. For instance, in contrast to most mammals, human sexual activities are typically present at any phase of the female menstrual cycle, and frequently involve sexual behaviors not aimed at conception, especially in committed relationships. It has been argued that one function of this adaptation is to foster long-term pair bonds on the basis of sexual intimacy and reward. It has also been suggested that the development of largely concealed ovulation in human females would have fostered enduring pair bonds, by making it harder for males to detect fertile phases and hence making it reproductively advantageous for males to remain with the same partner for extended periods of time (see Zeifman and Hazan 2016).

Further Reproductive Advantages of Pair Bonds

The adaptive benefits of strong affectional ties between mates may also have extended their role in infant survival. According to Zeifman and Hazan (2016), enduring pair bonds would have facilitated survival of mates themselves, since they increased the likelihood of being protected and cared for in the case of danger or sickness. Evidence also indicates increased reproductive fitness for mates by means of pair bonding. For instance, women in long-term sexual relationships display more regular ovulation and typically reach menopause later. Long-term romantic partners typically also display more robust physical and mental health, which generally would make them better able to provide for themselves and their offspring (Zeifman and Hazan 2016).

Moreover, enduring pair bonds have been suggested to foster the intergenerational transmission of advantageous mating strategies, and to increase reproductive fitness for offspring, by

leaving them better equipped to attract and retain mates of their own. Supporting this line of thought, long-term pair bonds are associated with better physical and mental health in offspring, and children of cohabiting parents are also typically better able to maintain stable pair bonds themselves (Zeifman 2019). In contrast, adolescents from father-absent homes typically become sexually active earlier in their psychological development and display more negative attitudes toward mates. Children of divorced parents also typically display more fear of closeness and abandonment, and are more likely to abandon relationships themselves (Zeifman and Hazan 2016).

Pair-Bond Functioning and Romantic Attachment Styles

Numerous studies have linked variations in relational and reproductive behavior to variations in romantic attachment style (for a more detailed account of romantic attachment styles, see ► [“Attachment in Adulthood”](#)). Many of the aforementioned findings have thereby partly been translated into attachment terms. For instance, romantic attachment security has been associated with higher stability and commitment in pair bonds, less likelihood of engaging in extra-dyadic sex, and more enjoyment from romantic relationships. Avoidant individuals, in contrast, often display lower pair-bond stability, more short-term reproductive behavior, and report less commitment and intimacy in romantic relationships. Findings for romantic anxiety have been more inconsistent but have overall indicated lower relationship stability and increased risk for unwanted pregnancy and sexually transmitted diseases in anxious women, and less frequent sexual activity in anxious men (Mikulincer and Shaver 2016).

Individual Differences in Pair Bonding: Attachment or Reproductive Strategies?

In Zeifman’s and Hazan’s (2016) account, the attachment system is held to be operative in long-term pair bonds, due to exaptation of the

attachment system in the course of evolution. The proposed function of this exaptation is to facilitate long-term pair bond mating strategies, which are thought to have generally superior adaptive value compared to short-term mating strategies. Romantic attachment styles are also thought to reflect variations regarding the presumed availability and responsiveness of the mate (i.e., attachment-related dynamics), with secure attachment typically being the most efficient for maintaining pair bonds.

Some of these notions have been contested by other theorists. For instance, Kirkpatrick (1998) has argued that considering the many external threats of the EEA, it would have been maladaptive for our adult ancestors to be heavily influenced by a behavioral system that evolved to promote protection through reflexive proximity seeking in the face of danger. Kirkpatrick also finds it unlikely that an entire behavioral system would be retained through development and yet undergo a qualitative change in its function. Hence, he rejects the notion that the attachment system is central for pair-bond functioning. Instead, he argues that the sexual mating system should be regarded as the primary behavioral system in romantic relationships, and that features related to the caregiving system – especially love operating as a commitment device – were co-opted by evolution to cement such relationships. Kirkpatrick and others (e.g., Belsky 1999) have also questioned whether long-term pair bonds really are of superior adaptive value. While long-term, investing strategies – aimed at maximizing offspring quality – might have been evolutionarily advantageous in resourceful and reasonably harmonious rearing environments, short-term and less investing strategies, aimed at increased offspring quantity, might have been more beneficial in harsher and poorer environments. Thus, rather than reflecting attachment-related variations, romantic attachment styles might reflect the reproductive strategies learnt to be the most adaptive in the individual's childhood environment.

In response, it has been argued that Kirkpatrick's view relies on an overly narrow definition of protection that fails to acknowledge normative developmental changes in the protective aspects of attachment. It has also been pointed out that

although associations exist between romantic attachment styles (secure vs. insecure) and mating strategies (long-term vs. short-term), the variation with regard to mating behavior is far too widespread within the different attachment styles for them to simply be reduced to mating strategies. Moreover, even if different mating strategies are adaptive in different environments, their outcome might not be equal with regard to long-term reproductive success. Just as the organized insecure forms of childhood attachment could be considered optimal adaptations to particular caregiving environments, but are sub-optimal with regard to long-term outcomes compared to secure attachment, short-term mating strategies have been associated with less optimal outcomes for offspring in a number of subsequent life contexts (Zeifman and Hazan 2016).

Leaving this dispute unsettled, it nevertheless highlights an important gap in existing research on adult attachment. As noted by Mikulincer and Shaver (2016), little empirical work has investigated the mutual influence of attachment, sexual mating, and caregiving systems on pair bond dynamics, and the available evidence does little to verify the presumed superior influence of the attachment system. Furthermore, while largely focusing on the respective importance of the attachment and sexual mating systems, the possible role of the caregiving system in pair bonding has received less interest from researchers. However, as noted by George and Solomon (2008), the importance of the caregiving system in rearing contexts is not restricted to females. Although gender differences likely exist regarding the interaction among behavioral systems, males can also be sensitive and involved caregivers, and throughout evolutionary history males have often also served a function in caregiving (Hrdy 2009). Thus, it seems possible that the caregiving system – operating in both females and males – has played a role in the evolution of pair bonds, facilitating joint parental investment by means of mutual concern for shared offspring.

Conclusion

Following selection pressures in human's primeval environments, pair bonds are thought to have

enhanced reproductive fitness for both infants and mates. It has been suggested that the attachment system, originally developed to secure infant protection from dangers, was exploited by evolution to foster such bonds. As a result, it has been argued, attachment-related dynamics play an integral role in romantic relationship functioning. This view has been supported by various theoretical and empirical findings. However, as illustrated by contesting views on the nature of romantic attachment styles, important research questions – not least regarding the interrelations between the attachment, caregiving, and sexual mating systems – still largely remain open.

Definition

Pair-bonding is an adult attachment relationship defined by a social preference for the pair-mate,

the distress upon separation, and the ability of the pair-mate to mitigate stressful situations.

Introduction

Pair-bonding is a behavioral construct central to adult human relationships and is also displayed in some other mammalian species (primarily ones which display monogamy as a social system). These other mammal species have given us the opportunity both to refine our definition of pair-bonding and to investigate its neurobiological substrates.

What is Pair-bonding and How do we Measure it?

Pair-bonding is a behavioral and psychological construct describing strong, enduring, selective social bonds between two adults. The concept is based on attachment theory as originated by Bowlby and Ainsworth (Bowlby 1969); however, they primarily applied this concept to infant-mother relationships, while pair-bonding is applied to adult dyadic relationships (Hazan and Shaver 1987). Pair-bonded adults (just like infants toward their mother) should display a preference for their familiar partner, distress upon separation, and lower responses to stress when in the company of their pair-mate (also known as “social buffering”) (Mason and Mendoza 1998).

Pair-bonding in nonhuman mammals has been well operationalized. The partner preference test was developed by Williams and Carter in the early 1990s (Williams et al. 1992). This test involves giving the test subject free access to three chambers: one which is empty, one containing the partner, and one containing a stranger of the same sex, and approximately the same age and weight as the partner. A partner preference is then defined as a statistically significant difference in the amount of time spent with the partner, higher than that spent with the stranger. The cohabitation time for the pair can be manipulated depending on whether you are experimentally testing a facilitation or an impairment of the bond. In other words, if you

want to know if your treatment increases the probability of forming a pair-bond, use a short cohabitation period; if you want to know if your treatment decreases the probability of forming a pair-bond, use a longer cohabitation period at least as long as the minimum time normally needed for bond formation.

Distress upon separation is typically measured by either distress vocalizations upon removal of the partner, increases in locomotion, or increases in the stress hormones cortisol or corticosterone. Finally, social buffering is measured by exposure to a stressor (e.g., handling) with and without the presence of the pair-mate. One caveat in these two measures is that experimenters rarely test the *specificity* of the social partner. For example, in order to really test whether an animal is distressed by removal of the pair-mate, the test animal should still have access to another familiar conspecific. This differentiates whether the distress is due to the missing pair-mate or social isolation. Other measures of pair-bonding have been suggested but not widely used, such as being willing to “work” to gain access to a pair-mate (Bardet et al. 2007).

What Other Mammals Pair-Bond?

In the animal world, pair-bonding is sometimes used interchangeably with the term “monogamous” or “socially monogamous,” or it is at least assumed that socially monogamous animals form pair-bonds. Social monogamy indicates a social system in which two adults and their offspring form basic groups. It is often, but not always, characterized by coordinated behavior between the pair-mates, defense of a mutual territory, mate-guarding behavior, and sometimes also male parenting. It differs from genetic monogamy, which is a mating system in which there are no extra-pair copulations, whereas most species branded as socially monogamous do display significant levels of extra-pair paternity. While most pair-bonds probably do occur in the context of socially monogamous species, social monogamy does not necessarily indicate the existence of a pair-bond. There is strong evidence for pair-bonding in remarkably few species, which we review below.

In the wild, titi monkeys (*Callicebus* spp.) live in nuclear family groups (a mated pair and their offspring) with coordinated activity, duetting of pair-mates, and mate-guarding (Mason 1968). Titi monkeys have also been well studied in captive settings. They display a preference for their partner in a classic partner preference test, although which pair-mate expresses a stronger preference may change over the course of pair-bonding (Carp et al. 2016). They display lower responses to stress when tested in the presence of the pair-mate (Hennessy et al. 1995), demonstrating stress-buffering effects. When the pair-mate is not present, they exhibit substantial distress (Mendoza and Mason 1986a), which is not attenuated by the presence of their infant (Mendoza and Mason 1986b) or an unfamiliar adult (Mendoza and Mason 1986a).

Prairie voles (*Microtus ochrogaster*), a classically monogamous species, in the wild display variations including monogamous families, communal groups, single female mothers with offspring, and wandering males (Getz and Hofmann 1986). It is unknown whether some of these variations are due to random circumstances (e.g., loss of a mate) or stable alternative reproductive strategies. Prairie voles do display all the hallmarks of pair-bonding in the lab, including a preference for the partner (Williams et al. 1992), distress upon separation (Resendez and Aragona 2013), and stress buffering (Smith and Wang 2014). While the specificity of the social buffering effects has not been well tested, “consolation” behavior is preferentially directed toward a pair-mate over an unfamiliar animal (Burkett et al. 2016).

Marmosets and tamarins, all members of the primate family Callitrichidae, display many interspecies similarities of social structure and behavior, with groups consisting of an adult pair, their offspring, and sometimes an additional reproductive unrelated or related adult (e.g., the brother or father of the breeding male, the mother or daughter of the breeding female) (Baker et al. 2002; Garber et al. 2016). Older offspring also help care for infants, making this a cooperatively breeding social system. Operational measures of pair-bonding have been tested in Wied’s

marmosets (*Callithrix penicillata*). During the first 3 weeks after pairing, these monkeys interacted more with strangers than with their partners during a preference test; however, by the end of 3 weeks, they interacted with both equally (Smith et al. 2010). After 8 weeks of cohabitation, females still spent more time in proximity with a stranger, while males spent equal amounts of time near their partner and a stranger (Cavanaugh et al. 2014). While it is possible that preference for the partner might increase over further development of the pair-bond, this cohabitation length was based on home-cage observations of affiliation (Agmo et al. 2012), suggesting that these may not always translate into a partner preference in a testing situation.

Marmosets show strong reactions to separation from their pair-mate. These separations are characterized by an increase in cortisol, which is attenuated by exposure to vocalizations from the pair-mate, but not by vocalizations from an unfamiliar animal (Rukstalis and French 2005). However, in male common marmosets (*Callithrix jacchus*), stress responses are buffered by familiar individuals such as a brother (Galvao-Coelho et al. 2012). Based on the evidence from this test and the partner preference testing described above, it seems less likely that marmosets have a strong, specific pair-bond.

Pair-bonds of other species which have been described as socially monogamous in the wild are less studied in captive settings, at least experimentally (e.g., the California mouse (*Peromyscus californicus*) and the owl monkey (*Aotus* spp.)). Mongolian gerbils (*Meriones unguiculatus*) do display the formation of a partner preference in females (only females were tested), whereas separation selectively affects males (Razzoli and Valsecchi 2006). Monogamous caviés (*Galea monasteriensis*) were similar; females developed a strong partner preference (only females were tested), while males displayed a separation response (only males were tested) (Adrian et al. 2008). In Siberian dwarf hamsters (*Phodopus sungorus*), males separated from their mates displayed a rise in cortisol as well as lower activity levels (only males were tested) (Castro and Matt 1997).

What Is the Neurobiological and Physiological Basis of Pair-Bonding in Other Mammals?

The neurobiology of pair-bonding is best studied in prairie voles. It is thought to involve co-activation of neurons for peptide hormones, oxytocin and vasopressin, and the neurotransmitter dopamine (Carter 1998; Gobrogge and Wang 2015). Briefly, oxytocin and vasopressin are involved in social memory, allowing for the selectivity of the pair-bond as far as which other individual is involved. During the formation of a bond, oxytocin acts on receptors in the nucleus accumbens in females, while vasopressin acts on V1a receptors in the ventral pallidum in males. Dopamine, a neurotransmitter involved in reward and addition processes, is also released into these areas. Its D2 receptors are present in the nucleus accumbens and ventral pallidum, and activation of those receptors facilitates the formation of the bond. Later, dopamine D1 receptors are upregulated and subserve the aggression which develops toward outsiders and functions to maintain the pair-bond. Mu opioid receptors facilitate the hedonic aspects of pair-bond formation, while kappa opioid receptors regulate the dysphoria of separation (Resendez and Aragona 2013).

The neural basis for pair-bonding in primates has been much less studied. Imaging of titi monkeys (*Callicebus cupreus*) indicates the involvement of the same neural areas implicated in rodent studies (Bales et al. 2007). In the same species, intranasal vasopressin in males increases contact with the female mate versus a strange female. In addition, agonism of mu opioid receptors and antagonism of kappa opioid receptors both decrease distress to separation from a mate (Ragen et al. 2015, 2013).

In common marmosets (*Callithrix jacchus*), oxytocin reduces interaction with an opposite-sex stranger, but only in females does it increase interactions with the mate (Cavanaugh et al. 2014). Treatment with oxytocin also made marmosets more attractive to their mates (Cavanaugh et al. 2015).

Conclusion

While arguments about whether or not humans are “monogamous” often take center stage, it is clear

that adult humans do develop strong, selective social bonds to each other. The study of pair-bonding in other mammals allows us to consider how experimental measures of pair-bonding would work in humans (without the use of questionnaires)! It also allows us to more fully investigate the neurobiological and physiological underpinnings of pair-bonding.

Definition

The study and interpretation of the fossil record of humans.

Introduction

Paleoanthropology is a subdiscipline within physical/biological anthropology that is devoted to the study and interpretation of the human fossil record. The fossil record includes not only the skeletal remains of human ancestors but other vestiges like fossilized footprints, endocasts (the natural or recreated casts of the brain), and stone tools or other artifacts. In the last decade, the study of ancient DNA (aDNA) has also progressed to become a significant contributor to paleoanthropological work.

Paleoanthropology

One of the primary goals of research in paleoanthropology is the reconstruction of evolutionary relationships, known as phylogenies, to better understand the relationships of various ancestor and descendant species throughout prehistory. This work has traditionally been accomplished through the study of various anatomical details found on the fossils themselves, which can provide clues to establish relationships between fossils and species. The addition of aDNA has enhanced our ability to understand relationships between more recent fossil groups, such as the Neandertals, and modern *Homo sapiens*.

Paleoanthropologists also examine the biology and behavior of human ancestors, and how hominins (humans and our ancestors) initially separated from the great apes. Bipedal locomotion has been recognized as the primary adaptation that separates a human ancestor from an ape. The origin of bipedality is quite controversial, with a variety of theories attempting to explain why humans would have adopted this posture and somewhat awkward form of movement. The earliest fossil humans include *Sahelanthropus tchadensis*, *Orrorin tugenensis*, *Ardipithecus ramidus*, and a variety of species of *Australopithecus*. Species joining us in the genus *Homo*, indicating similarities in body size, body proportions, and some behaviors, include *Homo habilis* and *Homo erectus*. Neandertals are typically referred to as either *Homo neanderthalensis* or *Homo sapiens neanderthalensis*, the latter suggesting a close relationship that would have allowed potential interbreeding with modern humans.

Paleoanthropology is a relatively young science, arguably tracing its origins to two key developments in the mid-nineteenth century. The first came in 1856 with the recognition of the first Neandertal fossil, discovered at Feldhofer's Cave in the Neander Valley in Germany (the word Neandertal refers to the location of this discovery, "tal" being the German word for valley). This first fossil skeleton forced scientists to confront the reality of ancient humanity, but at that time they lacked the theoretical basis to make sense of the find. In 1859, Charles Darwin provided that theoretical basis with the publication of *On the Origin of Species*. This seminal work laid the foundation for understanding the fossil record, and Darwin's 1871 book *The Descent of Man* addressed the evolution of humans specifically. The end of the nineteenth century brought a series of additional discoveries of fossil humans in Asia and Europe, further validating Darwin's predictions. The human fossil record now spans approximately seven million years, and includes dozens of fossil hominin species.

Advances in genetic sequencing technology, sampling, and computer processing have led to a revolution in the study of aDNA. The full nuclear

genome of the Neandertal has been sequenced and suggests that they may have interbred with humans (Green et al. 2010). These interpretations remain controversial, and more recent work casts some doubt on the potential for significant interbreeding (Fu et al. 2016; Mendez et al. 2016). Another exciting development has been the discovery of the Denisovans, the first human ancestor to be identified by its genetic sequence (Reich et al. 2010).

Conclusion

Paleoanthropology has illuminated many different aspects of our biological and intellectual evolution. The interpretation of fossil and archaeological evidence has been informed by a variety of scientists from different disciplines, with geneticists providing a series of important recent discoveries.

Definition

Early hominin species that lived in East Africa between 2.7 and 2.3 million years ago (mya) and is distinguished by its large teeth and jaws.

Introduction

Paranthropus aethiopicus is a species of early hominin that lived in East Africa approximately 2.7–2.3 million years ago (mya). Its designation as a hominin indicates that it is more closely related to modern humans than to any other living primate. However, this species lived alongside members of our own genus, *Homo*, and is thus believed to have gone extinct without contributing directly to the evolution of modern humans. Nonetheless, its study provides an important comparative context for our own evolutionary history.

Morphology and Evolutionary Relationships

Paranthropus aethiopicus is one of three hominin species distinguished by having more “robust” skulls than hominins of other genera. The “robust” traits of these skulls include large and thickly enameled postcanine teeth supported by deep and broad mandibles, zygomatic (cheek) bones extending both laterally and anteriorly, and the occasional presence of bony crests on the top and back of the skull, presumably for the

attachment of large jaw and neck muscles, respectively (Constantino 2013). Taken together, these traits suggest an animal that could both generate and dissipate high bite forces, and they imply that at least some portion of the *Paranthropus* diet was particularly difficult to break down (Rak 1983; Hylander 1988; Demes and Creel 1988). *P. aethiopicus* differs from the other members of its genus in having a more prognathic lower face (i.e., it projects further anteriorly), larger incisors, a shorter postcanine tooth row in a smaller mandible, a more posteriorly positioned sagittal crest, and a less flexed cranial base (Walker et al. 1986). These traits suggest a greater reliance on the anterior dentition, and along with features like a smaller cranial capacity (≈ 410 cc) suggest that *P. aethiopicus* may have evolved from the earlier *Australopithecus afarensis* (the species of the famous Lucy skeleton) (Skelton and McHenry 1992). Most paleoanthropologists agree that *P. aethiopicus* ultimately evolved into *Paranthropus boisei* (2.3–1.2 mya), which itself was broadly contemporaneous with the South African species *Paranthropus robustus* (1.8–1.2 mya).

Most paleoanthropologists recognize the distinctiveness of *Paranthropus* relative to other early hominin genera, but there is some debate about whether the species within this genus all evolved from a common ancestor to the exclusion of other hominin species (thus forming a monophyletic group) or whether the species from East and Southern Africa evolved from different ancestors in those areas. If they are not monophyletic, then the rules of taxonomic nomenclature state that they cannot be included in their own genus to the exclusion of others. Scientists who doubt their monophyly place them in the genus *Australopithecus*, along with approximately seven other species of less “robust” forms. Therefore, it is not uncommon to see this species listed as *Australopithecus aethiopicus*.

Key Specimens

Paranthropus aethiopicus is currently known from three sites including Laetoli in Tanzania, the Omo in Ethiopia, and West Turkana in

Kenya. Important specimens come from each of these sites, but the most well-known specimen is KNM-WT 17000 from West Turkana. It is a nearly complete cranium, though lacking in teeth. It is more commonly known as the “Black Skull” due to its dark color that reportedly resulted from high concentrations of manganese in the soil in which it was found. Other key specimens in the *P. aethiopicus* hypodigm include the mandible KNM-WT 16005, the mandible (and type specimen) Omo 18-18, and the maxilla EP 1500/01 (Arambourg and Coppens 1968; Walker et al. 1986; Harrison 2011). This latter specimen, from Laetoli, was the first of this species to be found outside of the Turkana Lake Basin. Moreover, it was found with a proximal tibia (EP 1000/98) – the first and only recognized postcranial element of this species (Harrison 2011).

Behavior

Most attempts to reconstruct the behavior of *Paranthropus* have focused on *P. boisei* and *P. robustus*, and with only one postcranial element confidently attributed to *P. aethiopicus*, we know virtually nothing about this species’ lifeways. There is even some lingering doubt about whether *P. aethiopicus* represents a valid species or whether it should be subsumed into *P. boisei*. Nearly all researchers accept there are differences between KNM-WT 17000 and the crania belonging to the *P. boisei sensu stricto* hypodigm, but there is less agreement about whether those differences justify a specific distinction between the two groups of fossils. The two studies that looked at this problem in detail have supported the validity of the species *P. aethiopicus* (Suwa 1988; Wood et al. 1994), but given the small size of the *P. aethiopicus* hypodigm, any solid conclusions about this species will need to await future discoveries.

Conclusion

Based on the evidence in the fossil record, *Paranthropus aethiopicus* originated at about

the same time as our own genus, *Homo*. Therefore, even though these hominins are not believed to be our direct ancestors, they may prove to be very useful for understanding our origins.

Paranthropus boisei

Paul Constantino

Department of Biology, Saint Michael's College,
Colchester, VT, USA

Synonyms

Australopithecus boisei; *Zinjanthropus boisei*

Definition

Early hominin species that lived in East Africa between 2.3 and 1.4 million years ago (mya) and is distinguished by its large teeth and jaws.

Introduction

Paranthropus boisei is a species of early hominin that lived in East Africa approximately 2.3–1.2 mya. Its designation as a hominin indicates that it is more closely related to modern humans than to any other living primate. However, this species lived alongside members of our own genus, *Homo*, and is thus believed to have gone extinct without contributing directly to the evolution of modern humans. Nonetheless, its study provides an important comparative context for our own evolutionary history.

Morphology and Evolutionary Relationships

Paranthropus boisei is currently known from at least eight sites in Ethiopia, Kenya, Tanzania, and Malawi. It is generally thought to have evolved from the earlier *Paranthropus aethiopicus* (2.7–2.3 mya) and been broadly contemporaneous with the South African *Paranthropus robustus* (1.8–1.2 mya). Together, these three species form a group that is distinguished by several morphological traits that give their skulls a more “robust” appearance than those of other hominins.

These traits include large and thickly enameled postcanine teeth supported by deep and broad mandibles, zygomatic (cheek) bones extending both laterally and anteriorly, and the occasional presence of bony crests on the top and back of the skull, presumably for the attachment of large jaw and neck muscles, respectively (Constantino 2013). *P. boisei* differs from the other members of its genus in being even more derived or “robust” in its skull features and having a more orthognathic (retracted) face (Rak 1983); the latter condition being one they share with members of our own genus *Homo* (Fig. 1).

Most paleoanthropologists recognize the distinctiveness of *Paranthropus* relative to other early hominin genera, but there is some debate about whether the species within this genus all evolved from a common ancestor to the exclusion of other hominin species (thus forming a monophyletic group) or whether the species from East and southern Africa evolved from different ancestors in those areas. If they are not monophyletic, then the rules of taxonomic nomenclature state that they cannot be included in their own genus to the exclusion of others. Scientists who doubt their monophyly place them in the genus *Australopithecus*, along with approximately seven other species of less “robust” forms. Therefore, it is not uncommon to see this species listed as *Australopithecus boisei*.

Key Specimens

The hypodigm of *P. boisei* consists of over 100 craniodental remains including the holotype subadult cranium OH 5 from Olduvai Gorge, the cranium KNM-ER 406 from Koobi Fora, and the mandible NMT-W64-160 from Peninj. Assigning postcranial fossils to this species has proven more challenging. A few have been attributed to *P. boisei* over the years (e.g., Grausz et al. 1988; Aiello and Porter 1990), but the only reported association of postcranial fossils with craniodental remains diagnostic of *P. boisei* comes from a single specimen from Olduvai Gorge (Domínguez-Rodrigo et al. 2013). The general picture that emerges from these limited

Paranthropus boisei, Fig. 1 Replica of a *Paranthropus boisei* skull (specimen OH 5) from Tanzania shown in (a) lateral, (b) anterior, and (c) inferior views

postcranial specimens is that of a muscular, terrestrially bipedal animal that may have continued to engage in arboreal behaviors. This behavioral reconstruction is not unlike those of other pre-*Homo* species, including members of the genus *Australopithecus*.

Behavior

When viewed as a functional unit, the “robust” skull traits of *P. boisei* suggest an animal that could both generate and dissipate high chewing forces, and they imply either that some portion of their diet was particularly difficult to break down or that they ate low-quality foods that required substantial chewing times. The latter hypothesis gained considerable support with the discoveries that *P. boisei*’s dental microwear shows no obvious evidence of hard food consumption (Ungar et al. 2008) and that this species had a carbon isotope signature consistent with extensive ingestion of tropical grasses and/or sedges (Cerling et al. 2011).

A lingering question about the behavior of *P. boisei* is whether or not they were capable of manufacturing and using stone tools. The dominant stone technology in existence during the time of *P. boisei* was called the Oldowan, and it

consisted mainly of hammerstones, cores (possibly used as choppers), and flakes used for cutting. However, most believe this stone culture was the product of the genus *Homo*, who was also around at this time and had larger brains than *Paranthropus*. Since all other great ape species and even capuchin monkeys use stone tools (Sanz et al. 2013), it is likely that *P. boisei* was capable of doing so as well. However, the question as to whether they could have intentionally modified and shaped stone to the extent that early *Homo* did remains open (Constantino and Wood 2007). Recent evidence of Oldowan tools at 3.3 million years ago (Harmand et al. 2015), prior to the appearance of both *Paranthropus* and *Homo*, is sure to reignite the debate.

Conclusion

Although *Paranthropus boisei* does not appear to be a direct ancestor of modern humans, knowledge of its paleobiology may prove critical in establishing the comparative context in which our genus evolved. Further discovery and study of these fossil remains may provide clues as to whether and how *Paranthropus* and *Homo* interacted, why the masticatory systems of *Paranthropus* enlarged while ours were becoming

smaller, and whether material culture was key in distinguishing the behavior of these two hominin groups. Ultimately, it may even help us to understand why *Paranthropus* went extinct while our own genus set off to inhabit almost the entire planet.

[Australopithecus robustus](#)

Definition

An extinct species (*Paranthropus*, meaning “beside-human”; *robustus*, “strongly built”) of South African hominins – bipedal human relatives from the Pleistocene Epoch (ca. 2.2–1.5 million years ago), possessing a small brain, small incisors and canines, and large postcanine dentition, considered a side branch of the human phylogenetic tree.

Introduction

Early in the twentieth century (the 1920s–1930s), three important discoveries were made in Southern Africa: the Taung Child – the first known *Australopithecus*; an adult specimen from Sterkfontein (then named *Plesianthropus*); and *Paranthropus* from Kromdraai. The latter discovery, together with later found similar fossils from Swartkrans, led to the understanding that not all “ape-men” (as they were called) were ancestors of humans, i.e., early on in the evolutionary history of hominins, a branching event occurred, from which two evolutionary lineages arose: one leading to us, humans, the other becoming extinct without leaving descendants.

Discoveries

The history of the discoveries of *Paranthropus* (generally referred to as a “robust”

australopithecine) dates back to 1938 when Scottish-born medical doctor, Robert Broom, then working as a curator at the Transvaal Museum in Pretoria, obtained the first fossil remains from the Kromdraai site. The specimen (TM 1517: partial cranium and mandible) was designated as the holotype of a new genus and species – *Paranthropus robustus*. In 1948, other remains were discovered at nearby Swartkrans (SK 6: mandible with teeth). Broom recognized this as being related to *Paranthropus* from Kromdraai, but on the basis of tooth size differences, it was assigned a new species name – *Paranthropus crassidens* (meaning “thick tooth”). Since then many specimens have been unearthed from the Swartkrans cave (e.g., Sussman, Grine [in:] Grine 1988; Grine, Sussman [in:] Brain 2004), making it the second largest site (after Sterkfontein) for hominin remains in South Africa. Currently, at least five “robust” australopithecine-yielding fossil sites are known. All of these were once caves (e.g., Brain [in:] Brain 2004) formed in dolomitic limestone, located about 10 km from Krugersdorp (near Johannesburg and Pretoria), which have recently been incorporated into the “Cradle of Humankind” (South African National Heritage site). The key *Paranthropus* sites are Kromdraai (yielding a dozen or so individuals), Swartkrans (over a hundred individuals), and Drimolen (tens of individuals, including a female skull – DNH 7), as well as Cooper’s Cave (partial cranium) and Gondolin (lower molar).

Dating

Unfortunately, the South African early hominin fossils are difficult to date because the cave sediments in which they are found are not suitable for the most absolute dating techniques. Therefore, their temporal distribution is not precise, being based primarily on faunal comparisons with other – East African – sites, biostratigraphy, and paleomagnetism. The age of the remains of *Paranthropus robustus* is estimated at older than 2.2 (Bruxelles et al. 2018) to ca. 1.5 Mya.

Morphology

In his earliest descriptions of *Paranthropus robustus*, Broom compared the morphology of the new fossil to that of extant apes and humans, and the fossils from Sterkfontein (*Australopithecus africanus*), and noted the differences in shape and size of the teeth and features of the temporal bone, palate, and face. He was intrigued by the anterior position of the cheeks, writing: “if a ruler be placed on the two cheeks the rest of the face is behind the ruler.” Since then, a number of monographs describing various aspects of the morphology of the “robust” australopithecines (see Fig. 1) have been published, partially or entirely devoted to the subject (e.g., Broom and Schepers 1946; Broom and Robinson 1952; Rak 1983; Kaszycka 2002). For a list of characteristic, diagnostic *P. robustus* features, see Table 1.

Taxonomic Views

Broom was a “splitter” – for the fossils from each site he was inclined to assign a new genus. Robinson (1954) simplified the existing classification, placing the South African hominin fossils into two genera and species – *Australopithecus africanus* and *Paranthropus robustus*. The former was

Paranthropus robustus, Fig. 1 Frontal view of the Swartkrans *Paranthropus robustus* cranium SK 48 (Photo by KA Kaszycka)

***Paranthropus robustus*, Table 1** List of characteristic *Paranthropus robustus* morphological features

Cranium
– Short and broad face
– Anterior position of the cheeks (zygomatic bones) with posterior placement of the midface (so-called dished face)
– Thin, arched supraorbital tori
– Frequent bony crests at the top of the skull (sagittal crest)
– Zygomatic arches broad, sagittally oriented
– “Anterior pillars” of the face (vertical bony columns bordering the nasal aperture)
– “Maxillary trigon” (triangularly shaped concave area of the infraorbital region)
Mandible
– Usually thick and robust corpus
– Tall and wide ramus
Dentition
– Small anterior teeth (incisors and canines) relative to posterior teeth (especially second premolars and molars)
– Low-crowned canines
– Premolars: P4 larger than P3
– Maxillary molars: M1 < M2 < M3 (with larger disproportion between M2 and M1 than between M3 and M2); high incidence of a Carabelli trait
– Mandibular molars: M1 < M2 < M3; mostly 6-cusped (on M3s usually more); high frequency of C6; low frequency of C7; high frequency of protostylid
– Mandibular deciduous molars: dm1, mostly 5-cusped; dm2, mostly 6-cusped (with C6 present)

described as “gracile,” i.e., lightly built, while the latter as “robust,” i.e., strongly built. Robinson argued that the generic distinctiveness of *Paranthropus* be retained, as he postulated that both taxa show adaptive and ecological differences. The specific distinction between *P. robustus* from Kromdraai and *P. crassidens* from Swartkrans was then reduced to a subspecific one – the two samples were separated on the basis of subtle differences in their deciduous teeth. Although later some researchers, e.g., Grine (in Grine 1988), restored the species-level distinction between the Kromdraai and Swartkrans samples (the Kromdraai specimens being less specialized), most current opinions hold that they are not taxonomically distinct (e.g., Kaszycka 2002). Findings from Drimolen (a nearby hominin-bearing fossil site) support the

hypothesis that all South African “robust” australopithecines are a single, though variable, species: the deciduous teeth of these remains have a considerable amount of morphological and metrical variation, showing similarities with the Kromdraai sample in some features and with the Swartkrans sample in others.

Dietary Habits

Early hypotheses about dietary adaptations of the australopithecines were based on anatomical features – the analysis of the size and proportion of their front to back teeth, as described in John Robinson’s 1954 classic “Dietary Hypothesis.” *Paranthropus* was then seen to be a vegetarian, while *Australopithecus* – an omnivore. Since the 1980s, microwear patterns on the molar teeth have been used to reconstruct the australopithecines’ food habits. Differences in the proportion of scratches and pits on the enamel surface of the molar teeth were revealed: the “robusts” showing more pits, which led to the conclusion that *P. robustus* ate hard food objects (e.g., Kay and Grine [in:] Grine 1988). Subsequent reconstruction of the hominins’ diet was based on direct evidence – isotopic analyses of chemical signatures in their teeth and bones. According to A. Sillen, the strontium to calcium ratio for the Swartkrans fossils appeared inconsistent with a herbivorous diet, suggesting an eclectic omnivory of *P. robustus*. From the stable carbon isotope ratio ($^{13}\text{C}/^{12}\text{C}$) in tooth enamel, it was possible to determine the kind of plants that were predominantly consumed. Carbon isotope values have shown a broader *P. robustus* diet in their consumption of not only C3- but also C4-derived food (e.g., Lee-Thorp and van der Merwe [in:] Brain 2004). Thus, such savannah-based foods as seeds and roots of tropical grasses, pith and tubers of grass-like plants – sedges, and/or the animals and insects that themselves eat these plants made up an important part of its diet. Underground storage organs, such as bulbs and corms, were also a possible source of nutrition. Lastly, it is possible that insects could have supplemented their diet. Today, therefore, it is accepted that *P. robustus*

Paranthropus robustus, Fig. 2 Upper molars of the Swartkrans *Paranthropus robustus* specimen SK 831a (top) compared with those of a modern human (bottom) (Photo by KA Kaszycka)

was most probably an omnivore, inclined toward herbivory, feeding on diverse plant foods requiring intensive mastication (see Fig. 2). In terms of its diet *P. robustus* was more generalist than specialist.

Tool Use

Chimpanzees have been frequently observed using (and producing) simple tools, so there seems scant reason to assume that *P. robustus* could not have. Modified fossil bones have been found at Swartkrans, which, by some (Brain and Shipman [in:] Brain 2004), are assumed to be *P. robustus* digging tools for edible plants' bulbs and corms while, by others (Backwell and d'Errico [in:] Brain 2004), to have been used for digging into mounds to extract termites. Brain's excavations at Swartkrans led him to conclude that these hominins were obviously not hunters, but rather the hunted (Brain 1981), possibly being the victims of predators, such as leopards (see Fig. 3).

Sexual Dimorphism and Mating System

A significant part of arguments for the accuracy of the reconstruction of the reproductive strategy of fossil hominins is derived from data on their sexual dimorphism. Prior to the discovery of the Drimolen skull DNH 7 by A. Keyser, which was smaller than any other *P. robustus* skull, it was generally thought that, in terms of body size, the level of sexual dimorphism of this species was relatively low (similar to that of the chimpanzee), while, in terms of cranial size, there was no significant variation. Later, it became clear that in fact *P. robustus* possessed a large level of size dimorphism. Recently, a study was published suggesting evidence of a difference in duration of growth between *P. robustus* males and females (Lockwood et al. 2007) – males maturing and achieving full body weight later than females (and young adult males being smaller than older ones). Combining this with estimates of a high degree of sexual dimorphism, the authors hypothesized a polygynous social system of extinct *P. robustus* similar to that of extant gorillas (i.e., one-male harems). This hypothesis, although attractive, was challenged on several points (Kaszycka 2016) – above all, “sexing” individual specimens and the uneven sex ratio in the available *P. robustus* sample. In consequence, the evidence for extended male growth seems doubtful, while the difference in duration of growth between males and females does not necessarily

imply one-male social groups. Therefore, although *P. robustus* exhibited an almost gorilla-like level of size dimorphism, a multimale–multifemale social system for these hominins was more likely.

Conclusion

We now know quite a lot about these cousins of our ancestors, yet there is still also much which is not known. We know that their adaptive strategy was that of powerful chewing. We also know that they became extinct, although we are unsure why.

The species from which *Paranthropus robustus* is descended is still a matter of debate – was it *Australopithecus africanus* or *Paranthropus aethiopicus*? A further question is whether the South and East African “robust” australopithecines are a monophyletic group (which would mean that the separate generic name would be justified) or a paraphyletic one (meaning that similarities within the group are based on homoplasies – independent evolution, not homologies – common ancestry).

Definition

A paraphilia is a preferred sexual interest (philia: love) considered to be unusual (para: outside the norms).

Introduction

Descriptions of paraphilias are highly controversial. In this entry, the concepts of paraphilia and paraphilic disorder will be presented. Correlates of paraphilias will also be described, along with a

proposition for a novel definition based on evolutionary criteria.

Official Definitions of Paraphilias

According to psychiatric diagnosis manuals, certain sexual interests (fantasies, urges, and/or behaviors) are uncommon, atypical, or anomalous (e.g., APA 2013). Typical examples of atypical sexual interests include voyeurism (observing an unsuspecting person who is naked, disrobing, or engaging in sexual activity), exhibitionism (exposure of one's genitals to an unsuspecting person), frotteurism (touching or rubbing against a non-consenting person), sexual masochism (being humiliated, beaten, bound, or otherwise made to suffer), sexual sadism (the physical or psychological suffering of another person), pedophilia (sexual interest in prepubescents), fetishism (sexual focus on objects or nongenital body parts), transvestism (cross-dressing), telephone scatologia (obscene phone calls), necrophilia (corpses), zoophilia (animals), urophilia (urine), klismaphilia (enemas), and coprophilia (feces). If these sexual interests are "intense" and "persistent" or greater than or equal to "normophilic" interests (i.e., "normal" preference or "interest in genital stimulation or preparatory fondling with physically mature, phenotypically normal, consenting human partners"; APA 2013), they are defined as paraphilias. If the paraphilia involves an illegal behavior or induces distress or impairment to the practitioner, it is viewed as the manifestation of a mental disorder (i.e., a paraphilic disorder; APA 2013).

These definitions are controversial, as they are based on assumptions that have not been demonstrated empirically. A first concern is the supposed rarity of some paraphilic interests. For example, fantasies and behaviors associated with voyeurism, couple exhibitionism, fetishism, masochism, and sadism are not statistically uncommon among adults (Joyal and Carpentier 2017). Therefore, certain paraphilic interests do not meet the basic criterion of being atypical. Another concern is the notion of intensity and recurrence of the sexual interest, as more than half of a nonclinical adult

sample reported some paraphilic sexual fantasies of equal or higher intensity than their "normophilic" fantasies (Joyal 2015). Maybe fantasies should not constitute a sufficient criterion to define paraphilia. A third concern is the unproven validity of the diagnosis given that signs of psychopathology are difficult to find among many types of non-offender paraphilic persons. For instance, a growing number of data suggests that persons practicing BDSM (bondage–discipline/domination–submission/sadism–masochism) possess equal, if not superior, psychological balance, educational achievement, and socioeconomical levels than the general population (e.g., Wismeijer and Assen 2013).

In addition, psychological distress associated with paraphilic interest results much more commonly from social negative perception and stigmatization than personal, inner, self-originating discomfort. Therefore, any definition of mental disorder should also include the effect of (and to) society. A fifth concern is the blur existing between legal and psychiatric criteria of sexual mental disorders. An illegal act per se (i.e., involving a non-consenting person) is not necessarily the manifestation of a mental disorder. In addition, legal definitions are unstable as they vary substantially across eras (e.g., oral sex) and cultures (e.g., homosexuality). Finally, the necessity of identifying precise sexual behaviors as symptomatic is not clear. It could be argued that any sexual interest inducing psychological suffering to the person should be considered as problematic, no matter its nature. In the next section, an attempt to better define paraphilia is made.

Defining Paraphilia from an Evolutionary Perspective

In 1992, Wakefield proposed a definition of mental disorder within an evolutionary perspective that unites biological and social perspectives. According to his definition, a condition is a mental disorder if it results from *the failure of a mental mechanism to perform its natural function* (biological or functional criterion) and if *it causes harm or deprivation of benefit to the person as*

judged by the standards of the person's culture (sociocultural or value criterion). As for paraphilias, they are traditionally defined in the field of evolutionary psychology as *any sexual behavior that diminishes or abolishes the odds of having a coital relation with a fertile person of the opposite sex* (Quinsey 2012). As stressed by Wakefield (2011), however, a sexual preference should induce a negative, undesirable or harmful effect on the individual *or on society as judged by social values* to be considered as paraphilic.

It is worth noting that these definitions still view homosexual behaviors as paraphilic (no coital relation and harmful effects on societies disapproving homosexuality). However, another sex-related and crucial function for humanity survival (and society cohesion) is the capacity to take good care of offspring. Giving the lengthy period during which human offspring are dependent on adults, biparental (or bi-adults or several adults in cases of adoption, reconstituted couples, and community living) caregiving represents an adaptive reproductive (and society cohesive) strategy almost as important as pregnancy. Selection pressures have produced physiological (e.g., oxytocin and vasopressin secretion) and psychological (e.g., emotions and affection) mechanisms to induce interpersonal attachment generated by sexuality. In turn, interpersonal attachment ensures the presence of adults to raise children, which improve their chances of surviving, well-being, and eventually reproducing compared with children of no parental or monoparental environments. Therefore, the odds of having an interpersonal sexual relation seem as important as those of having a coital relation. For instance, adopted children raised by infertile or homosexual but happy couples have much higher odds of future psychological well-being and professional success, on average, than children conceived by the rape of a fertile adolescent in a socioeconomic underprivileged environment (even if the latter sexual behavior theoretically helps species survival).

Thus, any exclusive sexual preference for behaviors not involving an interpersonal relation should be considered as suboptimal or undesirable from an evolutionary point of view. Exclusive paraphilic behaviors such as exhibitionism,

fetishism limited to an object, partialism without interest for the person, frotteurism, voyeurism, telephone scatologia, zoophilia, necrophilia, but also exclusive (and preferential) non-paraphilic behaviors such as exclusive (and preferential) solitary masturbation could be considered as problematic. Therefore, the exclusive and solitary (a preference to avoid interpersonal relations) qualities of a sexual behavior seem more important than its precise nature (paraphilic or not) to define optimal sexuality from an evolutionary perspective. For this reason, it is suggested to use the more general terms "disorders of sexual preference" (typical or not) than any specific paraphilia to describe suboptimal or maladaptive sexuality.

Paraphilia and Sexual Drive

Another motive to put emphasis on exclusivity rather than on the nature of a behavior in the definition of suboptimal sexuality is the fact that most paraphilic behaviors are associated with *higher general sexual drive*. Thus, although paraphilic behaviors are not by themselves coital, they are usually associated with *higher odds of having a coital relation*. Paraphilic interests are associated with low cerebral serotonin level (Kafka 1997). Low serotonin level is causally linked with higher general sexual arousal, behavioral impulsivity, thrill seeking, mood instability, and anxiety, all conditions that are commonly observed in persons with paraphilia. Testosterone, also associated with greater aggressiveness and sex drive, interacts with serotonin availability. These links between low serotonin level, high testosterone concentration, and high sex drive might partially explain why much more men than women develop paraphilia. Certain men might be more prone to associate nonsexual targets (e.g., inanimate objects or emotional experiences) with sexual arousal because they are more frequently and easily aroused sexually.

Indeed, paraphilic behaviors are rarely exclusive, and they should be placed on a continuum (e.g., from no interest for the behavior to exclusive use of it). When persons with paraphilic experience are recruited among the general population,

they commonly report greater sexual arousal, more diverse sexual interests (paraphilic and not), higher sexual orientation fluidity, and higher general sexual activity than non-paraphilic individuals (e.g., Långström and Hanson 2006; Joyal 2015). Paraphilic behaviors such as voyeurism, exhibitionism, and sadomasochism are associated with more (not less) lifetime sexual partners – contradicting traditional theories associating paraphilia with arrested sexual development or courtship disorders. BDSM practices, for instance, are obligatory for only a minority of practitioners, whereas a majority of players also enjoy “normophilic” behaviors. Many BDSM practitioners also report being as satisfied with their typical sexual activities as they are with their BDSM practices. Using pain or exposing genitals to strangers for sexual arousal is also associated with significantly higher (not lower) frequency of intercourse within stable relationships. In fact, Langevin and Lang (1987) found that exhibitionists usually have typical dating and sexual experience, many are married, and they enjoy intercourse.

Ironically, then, certain paraphilic behaviors might be associated with above-average reproductive fitness (i.e., increased number of lifetime coital relations with fertile partners), which would be evolutionarily adaptive. A notable exception is pedophilia, which not only involves a sexual focus on individuals that are not yet fertile but also is associated with higher odds of being single, living alone, and having no or less children, even when the pedophilic interest is not exclusive or have never been acted out. Frotteurism might also indicate a less favorable picture (more research is needed on the odds of coital behaviors associated with each paraphilia).

Sexuality and Psychopathology

Another reason to use the general terms “disorders of sexual preference” to define maladaptive sexual interests instead of specific behaviors is the fact that most paraphilic persons are not intrinsically distressed by their preferences, whereas any typical sexual interests could induce distress (e.g., an elderly distressed by his interests in oral sex or

frequent masturbation). Although a consensus exists to define a *distressing, necessary, compulsive* (i.e., *acted on urge, following a tension and producing relief*) and/or *uncontrolled* behavior as a psychopathological symptom, it should apply to any sexual behaviors, not only those defined as “paraphilic.” This way, any sexually distressed individual would receive treatment for a problem that is not currently listed in psychiatric manuals (distress caused by a typical sexual behavior or fantasy is considered neither as a sexual dysfunction nor as a paraphilia).

Sexuality and the Law

As for sexual behaviors involving a non-consenting person, they should be considered as crimes, whether or not they are listed as paraphilias (e.g., rape vs. voyeurism).

How Can Disorders of Sexual Preference Be Defined?

It is suggested to put more emphasis on the exclusive (or preferential) or psychopathological qualities of sexual behaviors and less on their precise nature (or legal statute) to define disorders of sexual preference. Therefore, the manifestation of a sexual mental disorder would have to meet one of the two criteria, derived from Wakefield’s definition:

- (A) To be any exclusive (no other sexual behavior is practiced) or frankly preferential (chosen more often for sexual gratification, even when coital relationship is available), non-coital *and* non-interpersonal (solitary or involving an unsuspected stranger or a non-human partner) sexual (leading to sexual arousal and/or sexual gratification) behavior (not only fantasies)
- (B) Any sexual behavior or fantasy inducing psychological suffering, i.e., distressing, rigid, obligatory, or compulsive (provoked by an irrepressible need to act out to reduce an inner tension or anxiety, perhaps followed by remorse, usually accompanied by both a

relief and a distressing feeling of loss of control) or occupational impairment (e.g., time, energy, or resources spent to complete the behavior affect other areas of life) to the individual practicing the behavior or having the fantasy

Conclusion

With this definition of disorders of sexual preference, emphasis is put more on the result of a sexual behavior (i.e., exclusively non-interpersonal or producing psychological symptoms) than its nature (paraphilic or not). Homosexual or infertile couples are not considered as maladapted, but pedophiles and child sexual abusers are. Consistent and preferential solitary masturbation from persons in couple would also be considered as problematic. As for all non-exclusive sexual behaviors involving non-consenting persons, they would be simply considered as crimes.

Definition

An organism that can either live in or on a host organism, and draws nutrients from the host, at the expense of the host organism.

Introduction

Within evolutionary biology there are many forms of parasites. Parasitism, a form of symbiosis, also takes many different forms throughout nature. Almost all life including humans, animals, and even microscopic forms of life can be susceptible to parasites.

An Evolutionary Overview of Parasites

Famous entomologist E.O. Wilson stated that parasites are “predators that eat prey in units of less than one” (Wilson 2014). What he means by this is that parasites do not follow the same standard procedure of the typical predator. While most predators hunt, kill, and then consume the entirety of their prey, parasites instead infect and live within or on their host. It is important to remember that the parasite, while still causing some harm, does not kill their host organism. In most cases, if the parasite killed the host organism, the parasite that has infected it would die as well. This leads to a parasitic relationship, which is a form of symbiosis, where the parasite gains all the benefit, while the host is harmed as a result.

Parasites, and parasitic infection, reduce the host’s ability to survive, and as an extension, reduces the host’s fitness. This is demonstrated in many ways in nature. Some of the most common forms are parasitic castration, which renders the host unable to reproduce, and behavior modification, which can take many different forms depending on the species afflicted. However, parasites increase their own fitness by taking resources from the host. Parasites reproduce considerably faster than their hosts, and rely on either actions of the infected host, or actions of a secondary host, in order to help in their transmission.

According to Poulin and Randhawa, “Parasitism is widespread in the animal kingdom, and has evolved independently from free-living forms hundreds of times” (Poulin and Randhawa 2015). Parasitic organisms can be animals, plants, fungi, protozoa, bacteria, and viruses. Some of the more common types of parasitic organisms that target humans include protozoa and worms. Infections caused by protozoan parasites include Malaria, different forms of dysentery, and African Sleeping Sickness. Parasitic worms such as tapeworm, hookworm, and whipworm target and reside within the large intestine where they are able to sap nutrients from the host. Symptoms from these infections can include lethargy, various digestive issues, and constant hunger.

Conclusion

Parasites include a wide range of various organisms that all share a common pathology. Further, parasitic relationships across organisms also share a common theme of the parasite gaining a benefit, while the host organism suffers.

Introduction to Parental Influence

Parental influence refers to the effects that parental (or caregiver) behaviors have on the development of offsprings' future behavior, preferences, and personality traits.

There is little debate that parents have a profound effect on the development of their

offspring. Indeed, human infants are among the most helpless newborn species and their survival to maturity is categorically dependent upon the presence and investment of parental caregivers. The first 5–7 years of a child's life is a time of considerable neuroplasticity, thus, depending upon what the child is exposed to during this time, parents will have considerable influence on the child's development across a variety of domains. These include the language a child speaks, the child's food preferences, the child's future religious beliefs, and, indeed, enduring aspects of the child's personality (Maccoby 2000).

The Role of Parental Investment

Compared with other species, human infants are notably fragile and vulnerable and, thus, require significant time, energy, and resources from their parents in order to survive to maturity. Within evolutionary psychology, the term “parental investment” refers to the quality and quantity of parenting children receive. In mammals, females tend to provide a disproportionate share of parental investment during early development. Fertilization and gestation occur within the female and women provide the primary nutritional support for developing infants until they are weaned. Although paternal investment may be little as the sperm contributed toward fertilization, additional forms of paternal investment may include provision of food and protection from predators (Bjorklund and Pellegrini 2000). Parental investment behaviors vary across species, depending upon the level of vulnerability of the newborn, but are considered critical for the survival of human offspring. Accordingly, insufficient or protracted parental investment (either prenatally or postnatally) will have dire consequences for a child's development. For example, teratogenic exposure during pregnancy and insufficient prenatal care have been linked with a host of neurodevelopmental delays in human offspring (Kundakovic and Champagne 2015). In the postnatal period, variations in nutrition, exposure to toxins, stress, neglect, abuse, and other adverse experiences have been linked with reduced cognitive functioning, protracted social development,

and an increased risk of developing a personality disorder as an adult (Johnson et al. 1999). Thus, at the most fundamental level, adequate and ongoing parental investment is critical to a child's development.

Attachment Theory and Parental Influence

Beyond providing food, shelter, and safety for developing infants, the relationship or attachment children form with their parents is also critical to their development. Unlike attachment processes in primates, where the primary function appears is to reduce infant mortality risks by keeping the infant close by, early human attachment processes with parents provide essential socialization skills and a stable interface for language acquisition, both of which are critical for successful functioning in larger social groups and securing a mating partner later on. In addition, "attachment-related behaviors," including stranger anxiety and separation anxiety, tend to appear at about the same developmental age across human societies, suggesting a strong underlying evolutionary history in attachment processes (Geary and Bjorklund 2000).

To this end, Bowlby (1969) argued that the attachment with the primary caregiver (typically the mother) is not only universal, but also critical to survival. Stable attachments with primary caregivers are thought to provide a "working model" for the initiation and maintenance of future relationships. Bowlby postulated that continued disruption with the primary attachment figure during the first 2 years of life could result in long-term cognitive, social, and emotional difficulties. Extreme cases of disruption with primary attachment processes, including the severe neglect experienced by institutionalized infants, have been shown to result in significant developmental delays, impaired cognitive functioning, development of autism-like behaviors, and increased circulating stress hormones (Kundakovic and Champagne 2015). These sequelae, in turn, protract normal psychological and social development leading to reduced reproductive fitness in adulthood.

Personality development is also influenced not just by the presence of a primary attachment figure, but also the *quality* of the attachment. In a series of experiments with infants and mothers, Ainsworth (1970) identified three, qualitatively different, attachment styles: (1) secure attachment (i.e., feels attachment figure can meet their needs, attachment figure is a safe base from which to explore the environment, can be soothed by attachment figure when in distress); (2) insecure avoidant attachment (i.e., ignore attachment figure when investigating a new environment, do not seek comfort from the attachment figure when distressed); and (3) insecure ambivalent/resistant attachment (i.e., demonstrate clingy and dependent behavior, difficult to soothe, have difficulty exploring environment). A fourth attachment type, disorganized attachment (i.e., unpredictable, erratic behavior; Main and Solomon 1990), was identified later on.

Ainsworth argued that a child's attachment style is largely dependent upon the behavior of the primary attachment figure. Thus, caregivers who are sensitive to their child's cues and can accurately identify their child's emotions and needs are more likely to have a child with a secure attachment than caregivers who ignore, misread, or are otherwise impatient with their child's emotional cues and needs. These variations in attachment style, in turn, may have downstream consequences for the child's development and future reproductive fitness. For example, some studies have linked insecure attachments in childhood with the formation of short-term, unstable pair-bonds in adulthood. Unstable attachment bonds in early childhood have also been shown to be predictive of depression in adulthood which would also undermine adult reproductive fitness potential (Bjorklund and Pellegrini 2000). In contrast, other studies have linked more secure attachments in childhood with more stable relationships in adulthood and greater parental investment in a smaller number of offspring (Rutter and O'Connor 2004). With regard to specific attachment types, disorganized attachments in early childhood have been linked with an increased risk of developing a personality disorder as an adult, particularly Borderline Personality Disorder (Carlson et al. 2009).

Conclusion

Adequate and ongoing parental investment provides critical resources for survival and reproductive fitness. Parental behaviors influence a number of preferences and developmental milestones. The quality of the attachment between child and caregiver plays a pivotal role in shaping expectations and behaviors in future interpersonal relationships with further implications for mental health and reproductive fitness in later adulthood.

Parental Effort Versus Mating Effort

Guy Madison

Umeå University, Umeå, Sweden

Synonyms

Parental investment vs. mating effort

Definition

Describes the trade-off between investing resources (e.g., time, money) in offspring already born or in mating to conceive more offspring. This is central to life history (LH) theory, where greater parental effort is associated with a slower LH strategy and greater mating effort is associated with a faster LH strategy.

Introduction

The distribution of resources into mating and parenting differs widely across species. But it may also vary within a species, subject to both genotypic, environmental, and situational influences. This variation is known as parental effort versus mating effort, here abbreviated as Parent/Mating. As predicted by parental investment theory (Trivers 1972), evolved sex differences are the most general and pervasive drivers of Parent/Mating within species (for humans see e.g., Galperin et al. 2013; Geary 2000; Verweij et al. 2016; Winking et al. 2007). Women are more selective in assenting to sex, are more agreeable and able to inhibit conflict-driving behaviors when required, and spend more time caring for offspring. These are but a few of an array of behavioral tendencies related to reproduction and attuned to interact with the social and physical environments. Cross-species and cross-cultural similarities as well as consistency with evolutionary theory indicate they are evolved mechanisms (see, e.g., Buss 2016 for humans). Another human universal is the tendency to engage in stable mating relationships,

which has important social, economic, and reproductive implications. Although the human pair-bond clearly confers advantages for the immature offspring compared to a single care-taker (see Geary 2000, pp. 61–65 for a review), the underlying selection pressures are not apparent. Prime candidates may be competition among males for mating opportunities, or fathers' parental investment. Some evidence is found for both, which suggests that the adaptive value of pair-bonds varies with the environmental context (Quinlan 2008).

Effort/investment is typically measured in terms of time, money, and other resources, either estimated or measured directly, or subjectively rated. Retrospective measures may also be applied. For example, parental investment could be indicated by the frequency of critical care activities across the first years of life. A general finding is that parents invest less in stepchildren than in biological children and that investment in stepchildren is more likely traded off for mating effort (Anderson et al. 1999; Marlowe 1999).

Many of the factors influencing Parent/Mating are addressed within the framework of life history (LH) theory, where greater parental effort approaches the slow (K) end of the LH continuum, and greater mating effort approaches the fast (r) end (Figueredo et al. 2005) (see Life History Theory for a detailed description). Specifically, persons at the K-end of the continuum seek to produce fewer offspring and provide more nurturing, whereas those at the r-end of the continuum produce many offspring without great investment in their welfare (Bjorklund and Shackelford 1999). These relations may of course be biased by evolutionarily novel environmental conditions, such as the incentives and subsidies provided by so-called welfare states (see Perkins 2016, for an example of such arguments). An early empirical study found a small association between an r/K dimension and Parent/Mating, consistent with LH theory predictions, based on measures of genitalia size, head circumference, strength of sex drive, intelligence, longevity, delinquency, sexual attitudes, and family size (Bogaert and Rushton 1989). However, parental investment in the current offspring may not always decrease the individual's ability to invest in future reproduction.

Male parental investment may function as a form of mating effort, by motivating females to have (additional) children (Anderson et al. 1999; Anderson 2011). For example, men will provide more care to their biological children as their mating opportunities decrease (Marlowe 1999). Theorizing in this area is constantly developing and becoming more complex, as more factors and their interactions are considered. Relevant factors for LH theory include caring and supportive, but also deceitful, delinquent, criminal, offensive, and violent behaviors, important for realizing adaptive tactics such as mate retention and competitor derogation (e.g., Figueredo et al. 2015). Nevertheless, it has been argued that individual variation, female investment, and interactions between the sexes are understudied in relation to Parent/Mating (Stiver and Alonzo 2009).

Studies of both sexes simultaneously find that maternal and paternal behaviors within the family vary between population subgroups and also across time. For both parents, larger family size is inversely related to the investment per offspring, even when high socioeconomic status would seem to allow for relaxing this trade-off (Lawson and Mace 2009). Considering female reproductive strategies, a study of 718 Western Australian women identified six dimensions: “short-term mating,” “early onset of sexual activity,” “reproductive output,” “timing of childbearing,” “breastfeeding,” and “child spacing.” The relationships between parental investment, reproductive timing, and overall reproductive success were consistent with LH theory. For example, women with a short-term mating strategy exhibited evidence for Parent/Mating between child quantity and child quality, but this was not the case for those with a long-term mating strategy (Milne and Judge 2012). Some women engage in short-term mating some of the time. Benefits that might be obtained from extra-pair liaisons include acquisition of resources, a better mate, mate skill, genetically diverse offspring, and mate manipulation. Greiling and Buss (2000) found the strongest support for mate switching and resource acquisition across a series of four studies. Similarly, women are more attracted to men high in Machiavellianism for short-term mating, but prefer men

low in this trait for long-term mating (Aitken et al. 2013).

Male reproductive strategies have been studied more extensively. Male Parent/Mating is affected by men’s self-perceived mate value and whether they are still in a relationship with the mother of their children. Men’s perception of their mates’ fidelity and their perceived resemblance to their offspring were also considered, both indicators of genetic kinship. Self-perceived mate value was positively associated with mating effort and negatively associated with paternal investment. Mating effort and paternal resemblance, but not mate fidelity, predicted investment for co-residing men. Mating effort and mate fidelity did not predict investment for separated men, but paternal resemblance was a strong predictor. Men with a low self-perceived mate value were less likely to reduce their investment in response to decreased mate fidelity than men with a high mate value (Apicella and Marlowe 2007). Similarly, facial attractiveness is positively related to mating effort, in terms of spending more time seeking sexual access and negatively related to spending it with kin. Less attractive men have more to gain by family involvement, either because it displays a potential for parental investment that is attractive to women for possible future relationships or because of so-called inclusive fitness, in which nepotism benefits shared genes (Waynforth 1999). The first of these explanations was supported by the finding that men of the Hadza foraging society in Tanzania trade off parenting effort for mating effort when facing better mating opportunities (Marlowe 1999). Evidence for male’s Parent/Mating is also found in the USA, in terms of a negative association between paying child support and having subsequent children. The fact that men who paid child support were more likely to remarry, however, suggests that child support payment functions as a display of parental commitment (Anderson 2011). A more specific test compared four classes of father-child relationships: (1) genetic offspring of current mates and (2) previous mates, and (3) step offspring of current mates and (4) of previous mates. Again, men invest more in their current mate’s children, regardless of whether the children lived

with him, suggesting that such investment functions as a mating effort (Anderson et al. 1999).

High mating effort is substantially associated with delinquency, promiscuity, and coercive sexual behavior. Offending is commonly used to gain and retain short-term mates, part of which includes fending off competitors. Self-reported delinquency and mating effort were correlated for both males and females, at about the same (0.5) magnitude (Charles and Egan 2005). Such behaviors are easier to perform if one is less empathic. The ability to recognize, manage, and appreciate emotions in oneself and others is sometimes called Emotional Intelligence. Accordingly, Emotional Intelligence was positively associated with slow (K) life history strategy, the end of the spectrum that correspond to high parenting effort and low mating effort (van der Linden et al. 2015).

Sex differences and individual variation in Parent/Mating presuppose a mediating mechanism. McGlothlin (2007) manipulated testosterone in wild birds and found that the level of this male sex hormone was positively associated with mating effort (aggressive response to a simulated territorial intrusion) and negatively associated with parental effort (nestling feeding). Thus, the bird model demonstrates how natural variation in testosterone or other androgens could mediate individual variation in Parent/Mating trade-off also for other species (McGlothlin 2007; Stiver and Alonzo 2009). The same effects of testosterone were found for human fathers, in a study also measuring the amount of caregiving, testicle volume, and neural activity related to nurturing. Caregiving was independently predicted by both testosterone and testicular size. When fathers were shown pictures of their own child, the activity in brain areas related to dopamine reward was negatively associated with testes volume (Mascaro et al. 2013).

LH theory also predicts that male Parent/Mating is affected by mate demand and supply, that is, the proportion of males to females in the population. On the one hand, a smaller number of males than females could enhance the males' short-term mating success and therefore make them less likely to commit by marrying. On the other hand, a larger proportion married of the scarcer

sex would confer the greatest overall mating success in terms of well-groomed and hence fertile offspring. However, males in industrialized societies tend to decrease their mating effort and increase their parental investment across the life course, presumably as a result of decreased circulating testosterone. Consistent with this, having a larger proportion of women in the population was associated with a lower proportion of men between 20 and 29 years of age being married, but a higher proportion of men between 35 and 74 being married (Kruger and Schlemmer 2009).

The nature and complexity of such dynamic interactions between the sexes can be addressed by computer simulation. Employing a game theoretic model, Dawson (1996) showed that Parent/Mating that was allowed to vary across the offspring (i.e., a realistic model) was evolutionarily stable only when one sex provides all parental effort. The inclusion of nonheritable variation in available resources to the individual made parental effort by both sexes an evolutionarily stable strategy (Dawson 1996).

Finally, Parent/Mating has been studied in relation to criminality. Two studies, one covering the Americas and one covering 39 countries across all continents, tried to determine whether regional variation in violent male criminality is explained by reduced parental investment of increased mating effort, in terms of mating competition (Barber 2006). Current crime incidences were analyzed in relation to the current single parenthood ratios and the historical single parenthood ratios 18 years earlier, allowing for the affected children to reach adulthood. Violent crime is best understood as a side effect of mating competition rather than an effect of reduced parental investment (Barber 2004, 2006).

Conclusion

Parental effort versus mating effort represents a fundamental adaptive problem for most animals. Although typically applied to differences across species, it has successfully been applied to study evolutionary mechanisms based on sex-, group-, and individual differences within the human

species. Situated in the midst of the nexus of human reproductive strategies, Parent/Mating constitutes an important tool that intersects with life history and parental investment theory. It is also powerful for understanding the behaviors of ourselves and others in everyday life.

Definition

Traditional theories of developmental and family psychology such as family systems theory (FST;

Cox and Paley 1997) focus on interdependent and bidirectional interrelationships among members of the household by viewing the family as a system and the members of the family as parts. According to this approach, interactions between members occur in predictable and repetitive patterns that provide internal balance to the family system. Any perturbations to the system (such as inclusion of new members into the household or loss of old members of the household, major life stresses, or changes that alter one of the relationships within the household) result in loss of homeostasis, creating household dysfunction. Family systems theory would thus view parenting and parental investment as influenced by and products of such household perturbations.

Evolutionary approaches such as parental investment theory (PIT; Trivers 1972) posit that the optimal allocation of resources to a current offspring is critically dependent upon the cost assessed in any consequent reduction in the quality or quantity of future offspring. Differential parental solicitude theory (DPST; Daly and Wilson 1987), an elaboration of PIT, discusses that the optimal allocation of resources to a current offspring is critically dependent upon the relative likelihood of the future survival and reproduction of the current offspring in relation to those of its past or present siblings. These theories (and the other evolutionary theories discussed below) view parenting and parental investment as coordinated strategies that weight short- and long-term costs in a manner that maximizes resources toward reproduction.

Introduction

Standard Social Science Model Approach. Traditional approaches toward developmental research agnostic to evolutionary modes of explanation, typically labeled the standard social science model (SSSM), have investigated the nuances of parenting and its impact on child outcomes for many years. One such nuance is the clear division of labor that occurs between the sexes (Coltrane 2000). Across all stages of childhood, mothers are more likely to devote

considerable time toward caring for children than are fathers (Bianchi and Milkie 2010). While secular trends indicate an increase in paternal time and effort toward child-rearing – with legislation both perpetuating and facilitating this trend – the data reveals that moms do more than dads. Inequitable partitioning of child-rearing duties and low agreement between parents on parenting has been associated with poor romantic relationship functioning (Greenstein 1996; Suitor 1991) and poor child outcomes (Erel and Burman 1995; Grych and Fincham 1990). FST, (Cox and Paley 1997) a predominant theory in family psychology, would posit that this pattern of associations occurs when one or more relationships within the household are dysfunctional and/or produce poor coherence and homeostasis. The foundational premise of family systems theory is that, because members of the household are highly interdependent, the dynamics of these interdependent relationships will have mutual and bidirectional influence on other members of the family. The family systems approach thus has a clear perspective on what is conceptualized as a “good” or “functional” system versus a “bad” or “dysfunctional” system; in contrast, an evolutionary approach approaches parenting and household functioning as not “good or bad,” which are considered relativistic terms, but as what is appropriate or conditional given the context (Ellis et al. 2012a)

The fundamental goal for individual organisms, according to the tenets of natural selection, is to survive and successfully reproduce. This involves surviving to sexual maturity and successfully acquiring, retaining, and reproducing with a mate; however for an organism to ultimately be successful, an organism must also have descendants that survive and successfully reproduce as well. Across different species, the amount of parental effort needed to produce reproductively viable offspring varies. Additionally, the actors who provide the parental effort to offspring vary (Hrdy 1999). In 5% of mammals, for instance, there is evidence for direct paternal care of young (Geary 2000). While many factors exist that modulate the level of effort in men and women within and across human societies, a

degree of complementarity exists between the sexes in raising children (Kaplan et al. 2001). From this perspective, men and women attempt to increase their reproductive output (e.g., healthy and reproductive viable offspring) through parental alliances, linking their reproductive success and dividing parental labor to maximize productivity (Kaplan et al. 2001). An evolutionary perspective, in contrast to the family systems perspective, hypothesizes that the amount of effort allocated toward parenting, the dynamics of the household, and the outcomes of such parenting all reflect one coordinated and cohesive parental investment strategy.

Evolutionary Psychology Approach

Analytical Systems Approach (Interactions of Individual Traits)

Whereas the SSSM typically uses a top-down *holistic* approach toward understanding family systems, where participants within that system are considered subordinate to the emergent properties of the system, evolutionary psychology (EP) instead adopts a bottom-up *analytical* approach to understanding family systems, where the emergent properties of that system are considered to be generated by interactions among the potentially different traits possessed by the participants in that system. Put simply, the top-down holistic approach focuses more on household and family dynamics without fully considering the impact of individual and phenotypic differences between actors in the household that produce the emergent household and family dynamics. Accordingly, the typical conceptual causal model of the SSSM posits: Family Effects → Child Outcomes. For example, Trivers' (1974) parent-offspring conflict theory (POCT; Trivers 1974) is simply not comprehensible in terms of a top-down and holistic family systems theory. POCT contends that discrepancies between parents and their children in the optimal allocation of parental care and effort expended will result in conflicts between them. Whereas investment and care from parents to their children is often assumed to be unconditional and limitless, the

time, energy, and resources to produce and care for children are limited in reality. From a parent's perspective, it therefore makes more sense to withhold a certain proportion of parental care and effort from current offspring to ensure that a portion of those resources can be allocated toward future offspring. From the child's perspective, it makes more sense to attempt to maximize the amount of care and effort they receive from their parents in order to gain a fitness advantage over their siblings. Trivers used a genetic estimate to make his point about POCT. A child is 100% related to itself, and any resources it can acquire will help improve its chances for reproducing. Any additional child a parent produces is assumed to be related to the current child by 50% for full siblings or 25% for half-siblings, eliminating the relatedness and, thus, the shared genetic interests the current child has on its offspring. For parents, all their biological children will be related by 50% to them so should have an equal "chance" for investment.

POCT is critically dependent on a bottom-up understanding of the individual participants within the family system as well as the relations among them. Only by analyzing the genetic coefficients of relatedness among the siblings, as well as between each sibling and the parent, do the dynamics of POCT make any sense, especially where half-siblings are present as their presence predicted more conflict between the mother and the focal child in the study independently of other household characteristics (Schlomer et al. 2010). These effects persisted whether or not there was a stepfather present in the home, suggesting independent mechanisms for POCT conflict for mother-child and father-child relations.

Nevertheless, both family systems theory and more sophisticated versions of POCT than the Trivers (1974) version require genetically informed and controlled studies to make conclusive statements (Ellis et al. 2012b). One approach to remedy this issue has been to use a *sibling design* where data is collected on older/younger sibling pairs raised in a single household. By collecting data on siblings, genetics and environment are genetically controlled and could thus allow for examination of specific events such as

father absence and its impact of child outcomes such as risky sexual behavior (Ellis et al. 2012b). Similarly, the genetic coefficients of relatedness used in EP to compare full with half-siblings are typically estimated at one-half and one-quarter, respectively. Under conditions of assortative mating, however, these coefficients may be quite severe underestimates (Wolf and Figueredo 2011); moreover, if a woman assortatively mates with the fathers of both the full and half-siblings on genetic similarity, the genetic difference between the full and half-siblings will inevitably be attenuated due to the genetic similarity among the fathers.

These limitations are also related to the diminished emphasis by the SSSM of gene-environment (G-E) correlations. G-E correlations may be generated by various mechanisms, including (1) passive, (2) active, and (3) evocative (Scarr and McCartney 1983). The existence of such correlations makes it impossible to think of causal relations within family systems as being purely top-down. For example, in evocative G-E correlations, the heritable traits possessed by the child may alter the behavior of the parents toward the child and thus skew the outcome of the family system generated by their interaction.

Context-Dependent Parenting

The SSSM perspective of what is “good parenting” (Cabeza de Baca et al. 2012) is context independent and reflects the cultural ideals of WEIRD societies (Western, educated, industrialized, rich, and democratic societies; Henrich et al. 2010). This includes parenting that is sensitive, warm, and highly involved, which is a characteristic parenting style of slow life history strategists (Cabeza de Baca et al. 2012). As such, this type of parenting tends to occur in highly stable and controllable environments. In stressful environments characterized by external and uncontrollable sources of illness and mortality, investing in high-quality parenting may result in diminished returns to reproductive fitness. In such stressful environments, parents should instead invest little in parental effort and orient their resources toward mating to maximize reproductive dividends.

As human beings and private citizens, most researchers agree that no child should suffer from abuse or neglect and should instead grow up in safe, loving households; however, as researchers, placing value labels on parenting strategies and child outcomes may have unintended consequences when put into practice such as in interventions. As mentioned, EP focuses on behavior and development as it pertains to the ecological context. In some contexts, certain behaviors and developmental outcomes may confer a selective advantage on survival and reproduction but may be considered contrary to what typical social norms are. Interventions that seek to reduce aggression or risk-taking behavior in adolescents from dangerous environments neglect the functional aspects of socially unacceptable behavior and may actually be “declawing the cat” (Ellis et al. 2012a, p. 610) or stripping away psychological and behavioral mechanisms that allow individuals to cope with their environment and/or gain status and access to resources present in their environment. Declawing the cat does nothing to alter the environment or situation in which youth reside. Evolutionists thus caution that interventions should thus target the ecology as a way to alter risky behavior and deleterious outcomes.

Parental Condition Dependent

The SSSM perspective of what is “good parenting” (Cabeza de Baca et al. 2012) is also condition independent, usually failing to consider the phenotypic conditions of either the parent or the child. Parental condition is important according to Trivers’ (1972) parental investment theory (PIT). According to PIT, a woman near the end of her reproductive career will likely suffer less cost in future offspring by investing heavily in current offspring and dramatically less in mating effort than a woman at the beginning of her reproductive career. This would, in turn, decrease amount of conflict between mother and child that is present in the household (Schlomer and Belsky 2012). Research examining breastfeeding duration, an indicator of maternal effort, presented evidence indicating that older and educated mothers report breastfeeding

longer than their younger, less educated counterparts (Davis et al. 2007).

Similarly, offspring condition is also a critical factor in Daly and Wilson's (1987) differential parental solicitude theory (DPST). According to DPST, an offspring who is a poor "bet" or bad investment (i.e., least likely to successfully reproduce) will be neglected in favor of redirecting any parental resources toward its more fortunate or promising siblings. Differential parental solicitude, according to Hrdy (1999), is unique to humans, when compared to other primates. Maternal abandonment of offspring and infanticide (directly enacting it or passively allowing it) occurs in nonhuman primates, but these instances are less contingent on child attributes or quality and more on resource availability, rank, and maternal condition (Hrdy 1999). Nevertheless, Hrdy (1999) documents the widespread problem of resource allocation among offspring faced by human mothers in hunter-gatherer as well as primitive horticultural societies. While not as pronounced, evidence of differential parental solicitude is found in WEIRD societies. Much research focusing on this phenomenon has been examined in preterm children based on their high risk of poor developmental outcomes. Using high-risk children allowed for testing the *contingent model of parental investment* (Bugental and Beaulieu 2003).

The contingent model of parental investment builds upon prior theory (e.g., Daly and Wilson 1987; Trivers 1972) by highlighting the interaction between parental and child condition on parental effort. The theory proposes that parents with poor conditions and low resources will decrease parental effort toward their child if they have poor condition and, hence, low reproductive prospects. Conversely, if a child with poor condition has parents who have resources and are in good condition, the child will receive more attention to improve and bolster his health status and advantage in becoming a viable mate. In a WEIRD sample of mothers and their infants, preterm infants received decrease maternal investment if the mother had higher levels of depression. In full-term infants, women with higher levels of depression actually showed

increased investment in their children (Beaulieu and Bugental 2008).

The *Trivers-Willard hypothesis* (TWH; Trivers and Willard 1973) is a special case of differential parental solicitude, as it posits that the optimal allocation of resources to offspring will vary systematically by the offspring sex, depending on the current condition of the parents and the predominant mating system of the species. For example, in a polygynous species, a mother in good condition is expected to produce more male offspring, as they are more likely to benefit more than female offspring from the extra resources in terms of increased mating opportunities; a mother in poor condition is expected to produce more female offspring, as they are less likely to suffer from decreased mating opportunities than male offspring when resources are diminished.

According to the hypothesis, parents will prefer investing in male offspring in stable, predictable, and controllable environments; conversely, harsh, unpredictable, and uncontrollable environments would shift parental investment and preferences toward female offspring. The rationale behind this set of hypotheses was that in low-quality environments, reproductive success was more likely with female offspring, guaranteeing an increase in grandchildren for parents. Intensity of competition for high-quality mates would increase in high-quality environments, emphasizing phenotypic quality and costly signals of fitness (Zahavi 1975). In these environments, a parent's best "bet" would be to invest highly in male offspring. While the losses would be great, the reproductive gains of having a male mate with multiple females (siring many children) would be greater. Evidence for the Trivers-Willard hypothesis (1973) in humans has generally been mixed, with parents in some societies generally favoring male offspring, parents in some societies generally favoring female offspring, and parents in other societies generally favoring neither (e.g., Freese and Powell 1999; Guggenheim et al. 2007). An investigation of maternal condition in a sample of Tucson households found that women living below the poverty level reported a greater preference for large female babies than male babies (Davis et al. 2007).

Normative Cultural Value-Based Versus Functional Fitness-Based Approach

As has been mentioned, evolutionary theory does not define parenting behaviors as absolutely “good” or “bad,” as has been traditionally denoted by standard social science models. In contrast, evolutionary theory views parenting behaviors as responses to ecological context and hence strategic and functional. From this point of view, parenting and household dynamics are thus considered the conduits to the outside world and reflect the ecological conditions the children will likely face in adulthood (Belsky et al. 1991; Ellis et al. 2009). From this perspective, parenting acts as modulator that modifies the development, behavior, and reproductive strategies of the offspring.

Conclusion

Although FST represents a major advance in understanding family dynamics within the SSSM, it suffers from the limitations of a purely top-down and holistic approach in failing to analytically break down the different condition-dependent and context-dependent roles of the participants within the family system. The EP approach offers a bottom-up reconstruction of the interactions among the members of a family system to derive more specific and testable predictions regarding the particular dynamics that one would expect from different combinations of participants under different ecological conditions. Insights from the EP approach include those offered by parental investment theory, differential parental solicitude theory, contingent model of parental investment, parent-offspring conflict theory, and Trivers-Willard hypothesis.

Parental Investment and Sexual Selection

Synonyms

Mate choice; Mate competition; Parental care; Parental effort

Definition

Parental investment, which occurs when parents provide costly investment that increases offspring survival, and sexual selection, which occurs when some individuals acquire more mates than others because of their traits, are highly connected. Differences in parental investment are often related to differences in sexual selection and can affect mate availability, competition, and choice. Here, we provide an overview of the link between parental investment and sexual selection.

Introduction

Parental investment (i.e., any investment by the parent in an individual offspring that increases the offspring's chance of surviving at the cost of the parent's ability to invest in other offspring; Trivers 1972) and sexual selection (i.e., covariation between mating success and the expression of sexually selected traits) are both major determinants of an individual's lifetime reproductive success. By investing into their offspring, an individual can improve the likelihood that offspring survive and reproduce, thereby improving the fitness (i.e., the relative lifetime reproductive success) of both the offspring and of the parent. Additionally, an individual can improve their own fitness by being selective about which individuals they mate with, in which case sexual selection can occur. Sexual

selection will act upon the traits that affect mating success, selecting for traits deemed as “attractive” by the choosy sex. This can span a variety of different traits including both physical attributes and behavior. Below, a brief overview of the link between parental investment and sexual selection is provided.

Parental Investment and Parental Care

Parental investment can occur in several different ways. In terms of prezygotic investment, gamete production is the primary form of parental investment, and both within and across species, females vary widely in the energy and resources that they invest into eggs. Post-zygotically, individuals can invest into their offspring via parental care. Parental care is often defined as parental behavior that occurs postfertilization, is directed at offspring, and appears to increase offspring lifetime reproductive success (Klug et al. 2012). Parental care is a form of parental investment when it is costly to the parent providing care, and the terms parental investment and parental care are often used interchangeably. Pre-zygotic and post-zygotic parental investment is incredibly diverse in nature (reviewed in Royle et al. 2012).

Sex Differences in Parental Investment, Mate Competition, and Sexual Selection

Sexual selection occurs when some individuals acquire more mates than others because of their traits, and sexual selection determines sex roles in a given system. Sex roles are considered to be (1) conventional when males are the mate-limited sex and compete more intensely for female mates and (2) reversed when females are the mate-limited sex and compete more intensely for male mates. Parental investment is a key driver of both sexual selection and the resulting sex roles in a given system, although we now know that sexual selection also influences the evolution of parental investment (reviewed in Kokko and Jennions 2008).

Parental investment differs in males and females, as females, by definition, produce larger

gametes than males and therefore contribute greater resources to eggs than males do for sperm. Because of this higher initial investment, a highly influential paper by Trivers (1972) suggested that females are more likely to provide parental care; however, more recent reexamination of this hypothesis has found that, from an adaptive perspective, current parental investment should not be based on previous investment and instead should be based only on the net benefits that a parent is likely to gain from that investment (see also discussion of the “Concorde fallacy” in Queller 1997 and Kokko and Jennions 2008). Thus, the differences in initial gametic investment between the sexes are not expected to directly determine the level of future parental investment that a parent provides. However, initial investment can influence a parent’s condition, for example, which will influence their likelihood of successful reproduction in the future, and the potential for future reproduction is expected to affect current investment in offspring. For example, if an individual has relatively little chance of reproducing in the future, we would expect them to invest heavily in current reproductive effort and current offspring.

If one sex initially provides greater parental investment in offspring (e.g., because of initial gametic investment, constraints, proximity to offspring, and/or reduced future reproductive potential), this can influence sexual selection. For instance, if providing parental care is associated with higher mortality than competing for new mates, the sex that provides parental care is likely to become rare in the population, and it will be difficult for the non-caring sex to find future mating opportunities. In such a case, coevolutionary feedback between providing parental care and competing for mates can lead to an evolutionary outcome in which sexual selection is relatively weak and both sexes provide parental care (Kokko and Jennions 2008). In contrast, if sexual selection is strong and mate competition is associated with greater mortality than providing parental care, the non-caring sex is expected to become relatively rare in the population. In such a situation, coevolutionary feedback between care and sexual selection would be expected to lead to

maternal care if females are the sex that initially provides care or paternal care if males are the sex that initially provides care (Kokko and Jennions 2008). Indeed, such scenarios highlight that (1) parental investment influences sexual selection and (2) sexual selection and the costs associated with mate competition can influence parental investment by males and females.

Multiple Mating and Parentage Can Affect Parental Investment and Sexual Selection

Another more recent study modeled the effect that parentage certainty can have on parental care. In some cases in which sexual selection is relatively strong on males, females might mate with multiple males, and this can lead to sperm competition and uncertain paternity. In cases where male paternity is likely to be uncertain due to multiple mating by females, males are expected to be less likely to provide parental care on a macroevolutionary scale (i.e., across species), creating a difference in parental investment between the sexes (Queller 1997; Alonzo 2010; Kokko and Jennions 2012).

In some cases, though, paternity certainty is unlikely to affect parental investment. For instance, within a species, males would only be expected to adjust parental investment in relation to paternity certainty if paternity certainty changes through a male's lifetime (i.e., if some reproductive episodes will be associated with greater paternity certainty; Alonzo 2010). Additionally, theoretical work suggests that when females are choosier, sexual selection will favor male parental care, regardless of paternity, such that females are more likely to mate with males who are better fathers (Alonzo 2012). This demonstrates that sexual selection alone does not explain the natural bias toward maternal care that is often observed in nature; rather, there are a variety of other factors that influence parental investment, including mate choice for parental care by fathers. Indeed, sexual selection in which females prefer mating with males who provide parental care has been observed in nature. For example, male care is sexually selected for in the sand goby (*Pomatoschistus*

minutus), such that females show a preference for males that provided more care (Lindstrom et al. 2006).

Time Out of the Mating Pool Post-Care Can Affect Investment and Sexual Selection

In addition to the above factors, the time in and out of the mating pool can also influence sexual selection and parental investment. For example, after mating, animals of many species cannot immediately remate because they (1) are providing parental care to current young and are unreceptive to additional mates and/or (2) are recouping energy or other resources required for mating. When some individuals are not able to immediately remate, the operational sex ratio (i.e., the ratio of males and females that are currently prepared to mate at a given time and place) can become biased. In such cases, biased sex ratios can either increase competition among members of the mate-limited sex or favor investment in parental care of current young (Parker and Simmons 1996; reviewed in Kokko and Jennions 2008).

Conclusion

Parental investment and sexual selection influence one another. In particular, parental care and mate choice and competition are expected to coevolve. Understanding why one sex might be choosier and why one sex might provide relatively more parental investment is complex and can be influenced by many factors, including parentage certainty, the costs of acquiring mates and providing parental care, constraints, proximity to offspring, sex ratio, and opportunities for future reproductive events. While much has been learned in the field of parental investment and sexual selection, there are still questions left to be expanded upon. In the future, it will be important to expand upon how these different factors interact with each other to lead to the origin and maintenance of different parental investment and mating strategies.

Parental Investment and Sexual Selection (Trivers Foundational Theory)

Definition

Where sex differences exist in relative investment in offspring, the sex that invests more is the limiting resource for the non-investing sex, resulting in differences in reproductive strategies and profound effects on morphology, physiology, and behavior between and within the sexes.

Introduction

Darwin's theory of sexual selection recognized that selective pressures could act differently on the sexes in ways that allowed individuals to effectively compete and pass on their genes. Darwin identified two main types of sexual selection: (1) competition within one sex for access to the other (e.g., male-male competition – weapons, large body size, aggressive behavior) and (2) differential choice by members of one sex for the

opposite sex (e.g., female choice – bright colors, elaborate plumage/pelage). What Darwin's theory lacked was a general framework that could explain and predict the interrelated variables and their consequences. Advances in evolutionary genetics, including Fisher's sex ratio theory (1958) and Bateman's (1948) work on variation in differential reproductive success (both within and between sexes) laid the groundwork for Robert Trivers' (1972) revolutionary work on parental investment and sexual selection. Trivers put forth an elegant model derived from basic economic principles to explain differences between the sexes based on reproductive effort. This theoretical framework can be used to explain a wide range of physical and behavioral differences between the sexes (Trivers 2002).

Trivers' Model

Trivers defined relative parental investment as “any investment by the parent of an individual offspring that increases that offspring's survival (and hence reproductive success) at the cost of the parent's ability to invest in other offspring.” (1972 pp. 139). Trivers concluded that the governing principle of sexual selection was the relative parental investment of the sexes in their offspring, beginning with the evolution of sexual reproduction and anisogamy (Trivers 1983). Anisogamy refers to the two distinct reproductive strategies within a species at the level of the gametes. One strategy is investing in fewer, larger, and relatively immobile gametes (e.g., eggs – quality over quantity). This strategy tends to involve extensive postconception investment (e.g., gestation, lactation, infant care in mammals) and is typically the female strategy. The second strategy is to produce massive numbers of small, inexpensive, mobile gametes (e.g., sperm – quantity over quality). This is most often the male strategy in mammals; there is usually little investment beyond insemination, and males mate often and with as many females as possible in order to maximize individual reproductive success. This creates intense competition for mates, typically between males, since fertile females are the limiting resource for individual

male reproductive success. This competition is compounded by variance in reproductive success observed among males in most species, where a few males father a disproportionate number of offspring in a given generation, while many males father none. Females typically benefit by being choosy because their return on investment is directly reflected in the genetic quality of the offspring.

Once Trivers established a coherent evolutionary logic, basic predictions of his theory could easily be tested by examining levels of parental investment by sex and associated behaviors and characteristics in insects, birds, fish, mammals, primates, and humans. Sex role reversed species, such as pipefish and spotted sandpipers, provided evidence confirming predictions based on investment strategy and not “sex” per se. In species, where males do the majority of parental investment, females are larger, more aggressive, more colorful, compete for access to males, and commit infanticide of rivals' offspring. Males in these species are choosy and only incubate and fledge offspring of certain females (Trivers 1985).

Conclusion

Trivers' theory of relative parental investment as the key variable controlling the operation of sexual selection has tremendous explanatory power for various physical and behavioral differences observed between and within the sexes. Some of these include differential mortality by sex, sexually dimorphic attributes such as brightly colored feathers and elaborate weaponry, sperm competition, different mortality by sex, and complex behaviors such as sexual jealousy, sexual coercion, infanticide, adultery, homicide, and cuckoldry.

Definition

Parental care is a strategy used to attract and select partners for mating.

Introduction

Parental investment can be understood as a mating strategy according to evolutionary theories. In some species belonging to animal kingdom, as well as in humans, the search for sexual partners considers characteristics such as sexual strategies, energy investment, and the chances of perpetuating genes. Thus, investment in parental care emerges as an effective strategy for attracting and selecting partners, primarily associated with long-term strategies.

Care for the Offspring as a Strategy of Sexual Competition

The human animal has primary goals for organizing their life, among them mating and genetic perpetuation. During the history of humankind, several parental and reproductive models were tested to reach more advantages and less disadvantages. The most perpetuated mating strategies are related to life history strategies, with short-term and long-term strategies. They would be characterized precisely by the emphasis given to the relationship, partner providing and fidelity (Giudice et al. 2015).

Sexual mating strategies are sets of adaptations that guide the investment and reproductive effort of an individual, defined as genetic programs or decision-making rules – conscious and unconscious – that individuals use to direct their efforts to behaviors that have specific objectives (Gangestad and Simpson 2000). Each sexual strategy influences how individuals choose and identify their sexual partners.

In a simplistic analysis, long-term strategies are usually associated with women, since they are the ones that need to invest more energy to carry and then ensure the survival of the offspring. While men are often associated with short-term strategies, they can quantitatively fertilize multiple partners simultaneously, without necessarily bearing the burden of women's energy investment, thus increasing their chances of reproductive success. However, men and women present short- and long-term strategies; gender differences

would only imply trends of more or less selectivity, not patterns. In addition, socio-environmental conditions, the search for good genes, and resources can influence the variability of the strategies adopted. It is in this context that the provision of parental care for the offspring, by men and women, presents itself as an important strategy for the effectiveness of procreation and genetic perpetuation. Both genders can benefit from this strategy; after all, parental care can contribute to offspring survival, success, and longevity (Gangestad and Simpson 2000; Shiramizu and Lopes 2013).

Parental investment comprises all forms of investment that parents offer in favor of offspring in a way that increases their chances of survival and reproduction (Gangestad and Simpson 2000; Manfroï et al. 2011). The provision of parental care is, on the one hand, a mating strategy and, on the other, a strategy for ensuring the generation of descendants. In species where there is a conflict of interest about reproductive strategies, as observed in mammal species, especially some species of primates, parental investment can serve as a way for males to conquer females. In the dispute between quality and quantity, offering care to the offspring can be an important success factor in the selection process of females (Smuts 1995).

There is a strong relationship between parental investment and sexual selection (intersexual attraction x intrasexual competition), which implies that the sex that invests more in the offspring tends to be more demanding in choosing sexual partners (intersexual attraction), while the sex that invests less would compete for the conquest of the opposite sex with more investor potential (intrasexual competition). Thus, the theory of sexual strategy considers that the choice of partners does not occur by what they may represent in the sexual act but by the role they may play as the father or mother of a future offspring (Borrione and Lordelo 2005).

It is possible to exemplify the relationship between intersexual attraction and intrasexual competition, with the fact that women necessarily invest more time and resources in the offspring, from the fertilization process to child care, which depends on the woman; thus, the female sex

would be more selective in the choice of possible sexual partners, which makes it the sex of greater intersexual attraction, whereas men are less discriminating and tend to exert greater intrasexual competitiveness (Buss and Schmitt 1993).

Despite there being a biological, evolutionary, and sociocultural justification for women to exert more parental investment on their offspring, men can also invest in their offspring from birth. When this occurs, it is possible that they are adopting parental investment as a mating effort and are also more selective in choosing their partners (Geary 2016).

Increased parental investment may be essential for the reproductive success of couples in diverse contexts, and it consists of multiple strategies of care, supply, and attention directed to the offspring. Some species depend on advanced levels of investment to achieve reproductive fitness, such as humans, who have prolonged gestational periods that result in an immature baby that relies on intensive and continuous care (Manfroï et al. 2011; Trivers 1972); however, other species of mammals and birds also require intensive care during and after birth.

Considering parental investment as part of a long-term sexual strategy, it is possible to identify advantages and disadvantages in its use, since it is a strategy that calls for monogamy and the choice of high-quality partners who invest in the offspring. For men the disadvantages are related to limited access to other partners, as well as the requirement for strict paternal care and investments; the advantages are linked to greater paternity certainty and the increase in the chances of the offspring to survive until reproductive age. For women, adopting the parental investment strategy has direct benefits, such as resources, protection, care, and transfer of status to the offspring; among the disadvantages faced by women is the fact that men with better genes are often not available for stable relationships (Gangestad and Simpson 2000).

Conclusion

Mating strategies differ slightly between the sexes. It is common for men to opt for short-

term strategies, while women are more likely to use long-term strategies. From an evolutionary perspective, it is possible to affirm that during the evolutionary process of human beings, men faced dilemmas between spending time and energy in raising children or in mating, while women are divided among the partners who offer parental care and have material resources or indications of good genes. Although the human species is characterized as a kind with high parental investment, the variability in the amount of parental investment offered to the offspring would be able to influence sexual selection of partners and the adopted mating strategy.

[Theory of asymmetric investment](#)

Definition

In most sexually reproducing species, the costs for reproduction are different for males and females.

Introduction

The great puzzle which Charles Darwin was bothered with but unable to find an answer to was why most animals reproduce sexually rather than asexually. In a publication on sexual selection in plants he states: “We do not even in the least know the final cause of sexuality; why new beings should be produced by the union of the two sexual elements, instead of by a process of parthenogenesis . . . The whole subject is as yet hidden in darkness” (Darwin 1861, p. 94).

Antoinette Brown Blackwell (1875) put forward a reason for sexual reproduction in her book *The Sexes Throughout Nature* that was largely ignored by the scientific community, only to be formalized and popularized about a century later: She describes the advantages of asexual reproduction, as long as the

environmental conditions are stable, but explains that as soon as environmental conditions change, the more costly sexual reproduction becomes the better solution. It took almost a century for this idea to be integrated in modern evolutionary theory: Leigh van Valen (1973) coined the term Red Queen hypothesis to describe the necessity of organisms to maintain genetic variability in unstable environments. In a sheer radiation of theoretical papers and mathematical models published in the following decade, the idea of sexual reproduction having evolved from the necessity to cope with unpredictable selection pressures was firmly established (Maynard Smith 1971; Glesener 1979; Hamilton 1980; Hutson and Law 1981; Bell 1982). The scientific impact of the Red Queen on biological and evolutionary studies in general continues to be fundamental. A concise and detailed description of the concept was published in 1990 by William Hamilton and colleagues (Hamilton et al. 1990).

Sexual reproduction rarely occurs with gametes of similar size. In most species, small and large gametes are produced, the small gametes by the male and the large ones by the female. Other than many of her contemporaries, Brown Blackwell does not limit parental investment to energy provided through the gametes and direct nutrition. She outlines the different ways how “parental love” can manifest and benefit the offspring.

Forms of Parental Investment

Through provision of nutrients in the egg, but also through feeding, the offspring is provided with essential nutrients. Direct nutrition is in many species biased toward the female sex, i.e., the female parent is the one who provides more in terms of direct nutrition than the male parent. This is due to the female gametes’ larger size and resulting higher production costs and nutritional value. In mammals, direct nutrition is also provided during gestation and through lactation, which leads to a very pronounced sex difference in parental costs afforded through direct nutrition. The impact of direct nutrition on the fitness of the

offspring is crucial in early development, but in the course of individual development, the relevance of direct nutrition falls back behind other forms of parental investment.

Direct nutrition, such as lactation, is provided almost exclusively by female parents, whereas indirect nutrition can come from both fathers and mothers. In many bird species, both parents share the burden of providing their hatchlings with sufficient food. The feeding of the offspring is a highly demanding activity, resulting in a substantial drop in weight in feeding parents, often below the weight of fully developed fledglings. In elaborate forms of parenting, fathers can provide food to mothers that is then turned into direct nutrition for the offspring.

Male and female birds take turns in incubating the eggs, thus sharing the parental load of investment. This can involve building nests where the eggs are taken care of, the costs of which can be shared equally or unequally. There are a large number of species where nest building is exclusively the task of the males. Some male fish nurse the eggs within their mouths, sit on top of them, or carry them around in pouches. Also in birds, there are some species where the bulk of parental care in terms of incubation and feeding is carried out by the males. If the majority of parental care is provided by the males, other aspects of the male and female organisms are affected, too. That is, females might be larger in body size, more colorful, and more competitive.

How Are Asymmetries Determined?

Which of both sexes manifests as the main contributor in parental care depends on the interplay of a number of socio-ecological factors. Other than the size of the gametes and the amount of direct nutrition, indirect nutrition, protection, and care can be taken on by both sexes to varying degrees. As parental investment can go far beyond the size of gametes and direct nutrition, a more differentiated view on parental care is needed to understand the sex roles and sex differences in different species. This integral view of parental investment also provides a much more flexible

basis for the manifestation of systems of investment. Asymmetries might end up less pronounced, or even reversed, depending on the socio-ecological conditions.

Reproductive costs do not equal costs arising from parental investment. Behavioral, physiological, and physical characteristics serving the purpose to persevere in intra- and intersexual selection also add to the complexity of costs of reproduction. Neglecting those in terms of parental investment might skew the perception of reproductive costs and lead to an unjustified emphasis of sexual dimorphisms. That is, the substantial costs of developing features that allow an organism to persist in intrasexual competition and to be successfully chosen in intersexual selection should not be ignored when estimating the costs of parenthood. Also, the focus on the size of gametes might be misleading: Usually, male organisms produce a much larger amount of small gametes than the females produce large gametes. The surplus of male gametes is a necessity to ensure fertilization. Therefore, the ejaculate, rather than the single sperm, should be the unit taken into account as minimal direct nutrition. This shift of perspective has been suggested by a number of authors but has as yet failed to take hold in the theoretical discourse (Hubbard 1997; Fausto-Sterling 1992, 1995; Tang-Martinez 1997).

The argument often fails to appreciate the complexity of the matter, either overemphasizing the role of direct nutrition or negating it, as Sarah Hrdy (1999) states. Anisogamy, if used too deterministically, fails to acknowledge facts as nutrition provided by the males either directly in the ejaculate or as bridal gifts, as well as the often essential role of male care for the survival of the offspring. On the other hand, criticism of the theory of anisogamy often downplays the biological costs of reproduction.

Robert Trivers's parental investment theory, as based on the principle of anisogamy, makes two profound predictions. First, individuals of the sex with the larger reproductive costs will be more selective in with whom they mate. Second, individuals of the sex with the lower parental investment will compete among themselves for

reproductive access to the other sex (Trivers 1972). There exist animal species where males invest substantially more than females, i.e., because the males provide nutrients or incubate the eggs. In these species, the males are more discriminating about mating, and the females compete among themselves for access to males. The seahorse males are exclusively responsible for the parental care after fertilization, carrying the fertilized eggs around in a special pouch until they hatch (Hrdy 1999). The male mormon cricket produces a large spermatophore that is packed with nutrient, thus costly to produce and their means to attract females, who compete for access to the males with the largest spermatophores (Buss 1999). In a number of spider species, sexual cannibalism serves as a form of parental investment: The female eats the male in the course of the mating act, which enables her to properly equip the offspring with nutrients. While this form of parental investment seems to be rather extreme, the cost of cannibalism to males may, in fact, not be unduly high, especially when compared to the alternative: In redback spiders (*Latrodectus hasselti*), approximately 80% of males die without mating in the wild, suggesting that being cannibalized does not necessarily reduce male fitness. Not all males are consumed by the female during mating, but if they are, they sire more offspring than if they escape (Andrade 2003). Sexual cannibalism also highlights the adaptive plasticity of parental investment: In most species where sexual cannibalism occurs, it falls far short of happening at all mating events. Resource potential of the habitat is one of the factors predicting the likelihood of cannibalism to occur: The threshold to eat their sexual partner is lower for hungry females than for well-nourished ones.

As the political and societal implications of parental investment theory are substantial, the necessary nuance in the discourse is often lacking. Evolutionary approaches tend to downplay the environmental effects, and social scientists tend to negate biological factors. Both positions in their extreme are wrong. If parental care can be negotiated, and asymmetries are not predetermined, sex differences observed in human behavior might be resulting to a lesser

degree from biological constraints than generally assumed. As is the case for human capacities in general, *Homo sapiens* is a species that belongs to the group of generalist rather than specialist organisms. Humans are highly adaptive and can handle a large variety of environmental challenges. There is no reason why this behavioral plasticity should not apply to human sexuality and reproductive behavior. Quite the opposite: The existence of monogamy, polygyny, polyandry, and promiscuous systems in different cultures indicates that the behavior complex of human reproduction is rather flexible (Low 2005). Socialization and cultural influences might contribute to the establishment and maintenance of so-called traditional sex roles. A need for disentangling the biological and socio-cultural influences is being recognized by more and more scientists, but as the bidirectional influences are complexly interwoven, a definite answer is not within reach yet.

Conclusion

The elegance of parental investment theory has led to a fundamental impact of that line of thinking on the questions addressed in evolutionary studies of human behavior: The resulting focus on intrasexual competition and intersexual selection makes it hard for some scholars to acknowledge the possibility of general competition among individuals, irrespective of their sex, when it comes to resources equally coveted by all.

As the theoretical framework affects the research practice, an interdisciplinary exchange can contribute to fend against bias. In interactions across disciplinary boundaries, the concepts inherent to the disciplines are continually tested, which sheds light on weaknesses in the argument and broadens the approach.

While complete objectivity is beyond reach for science, it should be the foremost intention of scientists to strive to minimize potential sources of bias and to keep an open eye toward biases that cannot be eliminated.

Parental Investment Theory (Middle-Level Theory in Evolutionary Psychology)

Xiao-Tian Wang
Psychology Department, University of South
Dakota, Vermillion, SD, USA

Synonyms

Parental care, parenting; Resource provision

Definition

Parental investment is referred to as any expenditure (time, energy, resources, etc.) that a parent incurs to benefit an offspring. *Parental investment theories* in evolutionary biology and evolutionary psychology explore mechanisms underlying parent-offspring relationships and investment. These theories examine adaptive functions and fitness dynamics of parent-offspring relationship, and how environmental conditions, sex differences in provision of reproductive resources regulate parental investment in sons and daughters.

Introduction

Throughout hominid evolution, our ancestors have always managed to do two things: survive to reproductive age and reproduce. Human survival and reproduction are characterized by internal fertilization, long-term gestation, lactation, and prolonged infancy that requires intense parental care and investment. *Parental investment*, in evolutionary biology and evolutionary psychology, is referred to as any expenditure (time, energy, resources, etc.) that a parent incurs to benefit an offspring (Trivers 1972).

From an evolutionary perspective, offspring are genetic vehicles for their parents. Without children, an individual's genes would perish. It is thus reasonable to expect that natural selection would favor powerful mechanisms in parents that ensure the survival and reproductive success of their children. Parental investment is thus pivotal for both offspring survival and perpetual reproductive success of the parents. Parental investment is viewed as a cost in parental fitness, via either direct physical or physiological expenditure or indirect opportunity cost in mating and reproduction.

Fisher's Principle

A pioneering analysis of parental investment can be traced back to Ronald Fisher. In his 1930 book *The Genetical Theory of Natural Selection*, Fisher developed an evolutionary model to explain why the sex ratio of most species that produce offspring through sexual reproduction is approximately 1:1 between males and females.

Fisher's model suggests that parental investment should also covary with this dynamic of evolutionary equilibrium. Fisher built his argument in terms of parental expenditure and predicted that parental expenditure may deviate from the 1:1 ratio but would be "corrected" back to an equal distribution by natural selection. Suppose females outnumber males in a population due to a war situation. A newborn male then receives more parental investment and would have better mating prospects than a newborn

female and therefore can expect to have more offspring. Therefore, parents who are genetically more disposed to producing males would have more than average numbers of offspring. As a result, male to female sex ratio becomes higher than 1:1. The demand and supply relationship thus is changed and then reversed: the shortage of males is replaced by a shortage of females. The male to female sex ratio is then downregulated toward the 1:1 equilibrium. Similarly, in situations that female births are less common than male births, the sex ratio would be regulated down toward the equilibrium (Hamilton 1967).

Regulated by natural selection, the total parental investment incurred will be equal across sex for children. This implication from Fisher's principle stands in contrast to persistent differential parental investment in sons and daughters. One way to understand the coexistence of the 1:1 sex ratio and differential parental investment is to view the former as population equilibrium and the latter as individual strategies that are dependent upon situational factors and the life-stage of the parents.

Sex ratio of an entire population is not as sensitive as operational sex ratio to natural selection and sexual selection. *Operational sex ratio* is a measure that is more sensitive to sexual selection. It is the ratio of sexually competing males that are ready to mate to sexually competing females that are ready to mate (Clutton-Brock 2007). This is a measure of how intense sexual competition is in a population and the potential rate of reproduction. This ratio reflects the severity of intrasexual mating competition and is controlled by relative parental investment (Gwynne 1990). For example, if females spend more time caring for young than mating, but males do the opposite, then more males would be ready to mate, thus creating a male-biased operational sex ratio.

Hamilton's Inclusive Fitness (Kin Selection) Theory

Parental investment theory can be viewed as a branch of kin selection theory. Building upon

Fisher's (1930) work, W. D. Hamilton (1964) proposed his inclusive fitness theory, which argues that altruistic acts toward neighbors who have copies of the helper genes would be favored by natural selection. Inclusive fitness theory holds the keys to understanding differential investment behaviors, including parental investment. The mathematical treatment of the theory ($C \leq rB$) is now often referred to as Hamilton's rule, which shows that an "altruistic design" can spread through the population if it causes an individual to help a kin member whenever the cost (C) to the helper's own reproduction is offset by the benefit (B) to the recipient's reproduction, weighted by the genetic relatedness between the two (r).

Hamilton's (1964) inclusive selection theory has been a powerful source for generating hypotheses about altruistic behaviors in social interactions, for which standard economic models fail to account. Hamilton (1964, p. 19) predicted that: "The social behavior of a species evolves in such a way that in each distinct behavior-evoking situation the individual will seem to value his neighbor's fitness against his own according to the coefficients of relationship appropriate to that situation." For kin selection to work, a prerequisite is that "a suitable social object is available" in an interactive social context (Hamilton 1987, p. 420). Parent-offspring interaction thus might be the most typical case for kin selection.

Hamilton's rule also suggests *extended forms of parenting* from kin who are not biological parents. For example, Gorrell et al. (2010) showed that surrogate mothers of red squirrels adopt related orphaned squirrel pups but not unrelated orphans. The authors of this study calculated the cost of adoption by measuring a decrease in the survival probability of the entire litter after increasing the litter by one pup and the benefit of adoption as the increased chance of survival of the orphan. More precisely, females adopted orphans when $rB > C$ but never adopted when $rB < C$.

Another form of extended parenting can be seen in *eusociality* (true sociality) which is characterized by overlapping generations between parents and their offspring, cooperative brood care, and the specialized castes of non-reproductive individuals (Freeman and Herron

2007). Social insects provide good examples of extended parenting. The workers of some species are sterile, a trait that would not occur if individual selection was the only process at work. The relatedness coefficient r is abnormally high between the worker sisters due to *haplodiploidy*, whereby males are haploid and females are diploid. This ensures that sisters are more related to each other than they ever would be to their own offspring. Hamilton's rule readily accounts for such extended parenting behavior, though there are alternative explanations (see Nowak et al. 2010).

Humans also exhibit extended forms of parenting. A study of childcare practices among Canadian women found that respondents with children provide childcare reciprocally with nonkin. The cost of caring for nonkin was balanced by the benefit a woman received – having her own offspring cared for in return. However, for individuals without their own offspring, the inclusive fitness benefits of providing care to closely related children might outweigh the time and energy costs of childcare. Indeed, the respondents without children were significantly more likely to offer childcare to kin only (Davis and Daly 1997).

Trivers' Model of Parental Investment

Inspired by seminal work of Hamilton (1964), Robert Trivers, then a graduate student at Harvard University, developed a theory of parental investment as a result of sexual selection. In *iteroparous* species, where individuals may go through several reproductive bouts during their lifetime, a tradeoff may exist between investment in current offspring and future reproduction. The importance of parental investment can be seen especially in species in which the offspring are altricial (i.e., unable to fend for themselves from earliest ages). In many bird species and in modern humans, this leads to males spending more time caring for their offspring than do the male parents of precocial species, since reproductive success would otherwise suffer.

Based on this cost–benefit analysis, Trivers (1972) defined the term parental investment to mean any investment by the parent in an

individual offspring that increases the offspring's chance of surviving (and hence reproductive success) at the cost of the parent's ability to invest in other offspring. Overall, parents maximize the difference between the benefits and the costs, and parental care will be likely to evolve when the benefits exceed the costs.

The evolution of sex differences in parental investment is widely attributed to anisogamy (i.e., sexual reproduction involving two types of gametes that differ in size). The initial asymmetry in premating parental investment (eggs vs. sperm) is assumed to promote even greater divergence in postmating parental investment (parental care). In such a situation, a male's reproductive success is limited by his ability to fertilize eggs with his sperm in the same-sex mating competition. A female's reproductive success is limited by her ability to produce eggs, which requires a large investment of metabolic energy (Trivers 1972, p. 138).

In humans, parental investment starts from the point when the sperm fertilizes the egg. Following fertilization, the minimal obligatory parental investment for the female is 9 months of pregnancy, followed by delivery. In contrast, the minimal obligatory parental investment for the male is almost zero. This difference of minimal obligatory investment between males and females suggests that the amount of investment and effort put into mating and parenting would also differ.

Trivers (1972) introduced two arguments to link premating and postmating investment. The first argument is that females are more committed than males to providing care because they stand to lose a greater initial investment. The second argument takes the reasonable premise that anisogamy produces a male-biased operational sex ratio leading to males competing for mates. Male care is then predicted to be less likely to evolve as it consumes resources that could otherwise be used to increase competitiveness.

These two arguments however are challenged by other scholars (see Kokko and Jennions 2008). The first argument has been criticized for committing the “Concorde fallacy” as optimal decisions should depend on future payoffs, rather than past costs. However, the argument can be made in

terms of residual reproductive value when past investment affects future payoffs. The second argument was challenged by the Fisher principle. Given each offspring has precisely two genetic parents, a biased operational sex ratio would generate frequency-dependent selection that favors increased parental investment by the sex facing more intense competition, in this case males.

Although facing some theoretical challenges, predictions from Trivers' (1972) model received ample empirical support. Using measures from time spent in vicinity, touching, and teaching children shows that women indeed care for their children more intensively than men do (Geary 2000).

Besides the mating opportunity costs hypothesis suggested above, another mechanism underlying the phenomenon that mothers invest more than fathers in offspring is the *paternity uncertainty* hypothesis. Mothers, consciously or not, are "sure" of their genetic contribution to their offspring (maternity certainty). When a female gives birth or lays a fertilized egg, there is no doubt that her offspring will contain 50 % of her genes. In contrast, from a male's perspective, there can always be some probability that the offspring was fathered by another male (paternity uncertainty).

Parent-Offspring Conflict

Given the importance of offspring, one of the astonishing facts about parental care is that many species do not engage in it at all (Alcock 2001). Part of the reason for the lack of universality of parental care is that it is so costly. By investing in offspring, parents lose out on resources that could be devoted to themselves or toward finding additional mates. Parents who protect their young risk their own survival. Thus, when fitness cost is higher than fitness benefit, a stopping mechanism becomes necessary.

From an evolutionary perspective, parents and children are predicted to have conflicts. Following his own work on parental investment and sexual selection, Trivers (1974) developed a model of parent-offspring conflict. In sexually reproducing species such as humans, parents and offspring are

genetically related by 50 %. This genetic relatedness between parent and child can exert selection pressure for parental care. But it also means that parents and children differ genetically by 50 %. Fitness benefit for one is not perfectly correlated with fitness benefit for the other. Specifically, parents and children will diverge in the ideal allocation of the parents' resources, the typical result being that children want more for themselves than parents want to give (Trivers 1974).

For a parent of two offspring with two units of food available, the optimal allocation would be to give one unit of food to each offspring. Considering that there is a diminishing return associated with each additional consumption, the value of the first unit of food consumed is higher than the value of the second unit of food. However, for each offspring, the ideal allocation is to get two units of food. The theory of parent-offspring conflict predicts that each child will generally desire a larger portion of the parents' resources than the parents want to give. In addition, parent-child conflict over the parents' resources is predicted to occur not merely at particular times such as adolescence, but at each stage of life.

Trivers' theory (1974) identified an important area of genetic conflict of interest between parents and children. Over evolutionary time, there will be an "arms race" between the genes expressed in parents and the genes expressed in children. Selection is therefore predicted to forge adaptations in children to manipulate parents toward the children's optimum resource allocation and counter-adaptations in parents to manage resource allocation toward their own optimum. This theory yields some surprising predictions. For example, mother-offspring conflict will sometimes occur in utero, such as over the blood supply to the fetus, the size of the fetus, and whether the fetus is spontaneously aborted. Empirical evidence supports these predictions (Haig 1993).

r/K Selection Hypothesis and Life-History Theory

The other overarching theory that is closely relevant to parental investment is the r/K selection

theory by MacArthur and Wilson (1967). According to the theory, when resources are sufficient to carry or support organisms living in an environment, organisms would be able to freely exploit rich resources for fast development and early reproduction that is characterized by a large number of offspring with little parental investment. This is known as *r* selection, with *r* representing the maximal reproductive rate of a species. In contrast, when resources become scarce, organisms adopt slow strategies, also known as *K* selection, with *K* representing the carrying capacity of the environment. *K* selection favors slow development and intense parental care and investment to reproduce few, high-quality offspring who can compete for and monopolize the depleting resources of the environment.

Species with *K*-selected traits, such as large body size, long life expectancy, and the production of fewer offspring, which often require extensive parental care until they mature, include elephants, humans, and whales. Although some organisms are identified as primarily *r*- or *K*-strategists, the majority of organisms do not follow this pattern (Hrdy 2000). The *r/K* dichotomy can be expressed as a continuous spectrum using the economic concept of discounted future returns, with *r*-selection corresponding to large discount rates and *K*-selection corresponding to small discount rates (Reluga et al. 2009).

The *r/K* selection theory has been challenged by its lack of empirical support and led to a newer paradigm of life-history theory that focuses on age-specific strategies and incorporates many of the themes important to the *r-K* paradigm (Reznick et al. 2002).

Life-history theory provides an evolutionary and psychobiological framework for studying parental investment. The theory primarily concerns tradeoffs among various survival and reproductive needs given finite energy and resources and infinite inter- and intra-species competition (Stearns 1992). The most essential tradeoffs are between somatic effort (growth, learning, and socialization) and reproductive effort. Reproductive effort itself involves the additional tradeoff between mating effort that results in offspring

quantity and parenting effort related to offspring quality.

Calibrated in terms of fitness or reproductive success, all tradeoffs can be summarized as the tradeoff between current or early reproduction and future or delayed reproduction. Varying along the fast-slow continuum, differences in life-history strategies result in the vast individual differences in observed behavior (Del Giudice and Belsky 2010). Variations in life-history strategies are the result of environmental conditions. Two overarching conditions relevant to life-history strategies are the extent of environmental harshness and unpredictability regarding mortality and mobility. High levels of extrinsic mortality and mobility lead to the adoption of fast life-history strategies with low parental investment because fitness is maximized by accelerating development and initiating early reproduction before extrinsic mortality or mobility hits. Conversely, low levels of environmental harshness and unpredictability do not necessarily predict slow life-history strategies but depend on other factors in the environment, such as resource levels and the extent of intraspecific competition over resources (Ellis et al. 2009). The most effective forms of signals in a child's environment are parental behavior and related information, such as the absence or change of parental figures (Ellis 2004). The mere experience of changes in parental and other adult figures has been found to be a robust predictor of fast life-history strategies (Tither and Ellis 2008).

Studies of life-history strategies suggest that quality of parental investment affects the adoption of fast or slow strategies by the offspring, which in turn determines the parental investment strategies of the offspring when s/he becomes a parent in the future.

Differential Parental Investment in Sons and Daughters

Trivers-Willard Hypothesis

Assuming an equal sex ratio in the population, sons and daughters, on average, have equal reproductive success. But the condition of the son or daughter might result in differential parental

investment in sons versus daughters. This is the core insight of the Trivers-Willard hypothesis (1973). According to this hypothesis, rich parents are more likely to have successful offspring and should favor sons since there is a greater opportunity for their sons to be rich and to have more offspring. Conversely, poor parents should prefer daughters to sons because daughters are not as likely to be reproductively unsuccessful as sons.

Stated differently, if being in “good” condition affects male reproductive success more than female reproductive success, as we would expect in a polygynous mating system, then parents should bias investment toward sons if the parents are in good condition and toward daughters if the parents are in poor condition.

Tests of the Trivers-Willard hypothesis in humans have proved inconclusive (Keller et al. 2001). A few studies find a Trivers-Willard effect. In one study, for example, using years of education as a proxy for parental investment, Rosemary Hopcroft (2005) found that sons of high-status men attained more years of education than daughters, whereas daughters of low-status men reached higher education levels than sons. She also found that high-status men sire more sons. Future studies are needed to determine whether the hypothesized Trivers-Willard effects are found among different populations of humans. Gaulin and Robbins (1991) found support for the Trivers-Willard hypothesis in their study of North American women. However, additional tests of this hypothesis have produced mixed results, particularly with human samples. In a study with larger data sets, Keller et al. (2001) reported that their results did not replicate the findings of Gaulin and Robbins (1991). Based on the analysis of the results from their own and other previous studies, these authors conclude that Trivers-Willard effects are at best tiny in the contemporary United States, where resources are too abundant compared to the typical conditions of hominid evolution.

Reproductive Variance Hypothesis

An alternative account of differential investment in sons and daughters focuses on the reproductive variance of sons versus daughters. The concept of

variance in reproductive payoffs has been pivotal in some recent evolutionary analyses of behavior (see, for example, Daly and Wilson 1997). The evolutionary logic for risk/variance sensitive strategies is that selection would favor a greater risk-proneness when risk avoidance promises not fitness but reproductive failure. Universally and throughout hominid evolution, men have a higher reproductive variance than women. That is, women tend to consistently produce a few children whereas men tend to have either a lot of offspring or zero offspring. From a Darwinian perspective, risks can be viewed as variance in reproductive fitness in terms of the number of offspring one has (Wang 2002). Thus, parental investment in daughters versus sons is like a risky choice between a safer bet and a gamble (a more probabilistic bet), respectively.

Following this line of thinking, parents from a contemporary US population whose wealth conditions are not clearly diversified tend to have comparable parental expectations (aspirations) for their children’s financial and reproductive prospects. Thus, what affects their differential investment in sons or daughters would be their psychologically perceived relative wealth compared to their neighbors instead of absolute wealth. When the perceived relative wealth is lower, the distance to parental expectations would be higher. Thus, sons would be favored since a higher variance in sons’ financial and reproductive success would increase the chance of reaching the parental expectations or goals. Conversely, daughters would be favored by parents who have a higher perceived wealth. Therefore, a reversed Trivers-Willard effect is likely to be found in a less stratified population as a result of the difference in perceived relative wealth. In contrast, a Trivers-Willard’s effect would be more likely to be found in a population with a stratified wealth structure. For instance, if a wealthy parent has a much higher than average expectation for his or her children’s financial and reproductive success, sons would be favored, thus a Trivers-Willard’s effect.

In a field study conducted in villages in north-west China, Wang (2002) found a reversed Trivers-Willard’s effect when perceived wealth

condition (rated on a 1–9 scale against families in the same local area) was taken into account. The interbirth interval as a measure of parental investment was significantly longer after having a son than after having a daughter for the families with lower perceived wealth but not the families with higher perceived wealth.

In another field study conducted in a Midwest U.S. rural community where the wealth structure was also unstratified, Wang (2007) found that actual household income affected overall parental investment in a child irrespective of the sex of the child, using breastfeeding and interbirth interval as the measurements of the degree of parental investment. In contrast, perceived wealth by parents relative to their neighborhood households affected differential investment in sons versus daughters. Independent of real income of the family, IBI was longer if the parents' perceived family wealth was lower. This effect of perceived wealth on IBI was evident both for daughters and sons. As predicted from sex-specific reproductive variance, a differential breastfeeding pattern in sons and daughters emerged. In the families of higher perceived wealth, the average percent of daughters being breast fed was significantly higher than that of sons (67 % vs. 36 %). In contrast, in the families of lower perceived wealth, the percent of daughters being breast fed decreased to 52 % and the percent of sons being breast fed increased to 49 % percent.

The results from these two studies suggest that investing in sons is riskier than investing in daughters. In terms of parental economics, sons can be viewed as a riskier prospect than daughters since men, on average, have a higher variance in wealth and reproduction than women.

Conclusion

Parental investment theories in evolutionary biology and evolutionary psychology have provided overarching frameworks and testable mechanisms that lead to novel predictions about parent-offspring relationships and investment. *Fisher's model* focuses on the natural selection mechanism that maintains the 1:1 equilibrium in sex ratio and

how parental investment covaries with the dynamic of the equilibrium. *Hamilton's inclusive fitness model* reveals the production rules for the evolution of cooperation between kin, including boundary conditions for parental investment. *Trivers' model* identifies a link between parental behavior and sexual selection, and sex-specific differences in reproductive resource provision before mating and post-reproduction. Since that parental investment is costly for the parents and that the genetic relatedness of a child to either of the parents is 50 %, the ideal resource allocation for a child does not coincide with the ideal resource allocation for the parents. Thus, parent-offspring conflict is inevitable and ubiquitous. *Parent-offspring conflict theory* thus provides unique predictions for parental investment related behaviors. The *r/K selection model* and *life-history theory* view parental investment as an adaptation to environmental harshness and unpredictability regarding mortality and mobility. Evolutionary analyses also help to understand *differential parental investment*. The concept of *paternity uncertainty* is used to account for one type of differential parental investment that mothers invest more in offspring than fathers. The *Trivers-Willard hypothesis* predicts another type of differential investment in sons versus daughters by the parents, contingent upon the wealth condition of the parents. An evolutionary analysis based upon *reproductive variance* in sons versus daughters offers an alternative mechanism for understanding differential parental investment.

Parent-Offspring Conflict

Amy Jacobson
Monmouth University, West Long Branch, NJ, USA

Synonyms

[Conflict over parental investment](#); [Maternal-fetal conflict](#); [Weaning conflict](#)

Definition

Using a gene level view of evolution, offspring and parent obtain equal status. The parent is related to each offspring equally with a 50 % probability that any gene in the parent is also found in a given offspring (e.g., degree of relatedness $r = .5$), while the offspring is related to itself by $r = 1$. This creates inherent levels of conflict over investment between parent and offspring, from conception in the form of maternal-fetal conflict to weaning conflict in early childhood as well as the molding of altruistic, egoistic, and reproductive tendencies of offspring into adulthood.

Introduction

In “parent-offspring conflict,” Trivers (1974) expanded on Hamilton’s kin selection logic of viewing relationships between individuals in terms of their genetic interests. In doing so, he recognized that the interests of offspring almost inevitably come into conflict with those of the individual parent. Parents share the same amount of their genes with each offspring ($r = .5$) and therefore should equally invest in their survival. Offspring, however, benefit by seeking to extract as much parental investment as possible for themselves, at least up to the point where the resulting

Parent-Offspring Conflict, Fig. 1 Conflict during the period of investment over the amount of investment. The benefit (B) or the cost (C) of investment at a given moment is plotted as a function of the amount of parental investment. The parent is selected to maximize the difference

between the two functions (B and C); that is, to invest P . The offspring maximizes ($B - rC$) (here $r = 1/2$); that is, it is selected to receive investment O . (RS reproductive success; IF inclusive fitness) (From Trivers 1985)

damage to their siblings begins to decrease their own inclusive fitness.

This was revolutionary in that classic evolutionary theory had traditionally viewed the parent-offspring relationship exclusively from the perspective of the parent. This interpretation assumed that parents would be selected to allocate their resources in ways that maximize their individual reproductive success, offspring serving merely as passive vessels into which this investment was deposited.

Recognizing offspring as active participants in the process of reproduction, the inherent conflict based on discrepancies of individual genetic interests, and key concepts of inclusive fitness allowed Trivers to generate a theoretical model of parent-offspring relations that could be used to explain the evolution of many complex interactions and behaviors within families (Trivers 1985, 2002).

Conflict Over Continuation of Parental Investment

Trivers made predictions based on economic modeling of when and where periods of conflict over resources between parent and offspring would occur. Weaning conflict in mammals and fledging conflict in birds were some obvious

examples. Trivers identified the period at which the mother would be selected to cut off investment to an individual offspring in terms of maximizing her own RS by ceasing investment in milk production so as to resume ovulating in order to conceive again. The offspring, however, being related to itself by $r = 1$, but to future siblings by $r = .5 - .25$ (depending on whether they share genes from a common father), devalues the cost of nursing and therefore would be selected to agree to be cut off at a date later in time when the costs to him in terms of inclusive fitness outweigh the direct benefits (Fig. 1).

Under this model, individual offspring would be expected to evolve a range of tactics to induce more investment from the parent, than the parent would be selected to give. This, Trivers argued, is why human babies throw tantrums, infant monkeys attack their mothers when they withhold breast milk, and bird chicks threaten to harm themselves when parents refuse to feed them (Trivers 1974, 1985, 2002).

Conclusion

Trivers' approach to the parent-offspring relationship from the view of genetic interests and

individual reproductive success is powerful in that it can be used to explain such diverse phenomenon as maternal-fetal conflict over resources in the womb (see Haig 1993), as well as the intricacies of social relationships within the family. Trivers argued that much of human socialization of children is influenced by conflicts of genetic interests where parents act in ways to increase altruistic tendencies in their offspring toward each other, while reducing selfish and egotistic behaviors that create conflict within the family. While this may decrease the individual offspring's reproductive success, it is selected for in the parent because it benefits them in terms of inclusive fitness (Trivers 2002).

Parent-Offspring Conflict (Trivers)

James Malcolm
University of Redlands, Redlands, CA, USA

Definition

The genetic interests of parents and their offspring are not identical. Offspring can be expected to

want more investment than their parents are selected to give them.

Introduction

Human infants cry. The noise seems louder than is necessary given the typical distance to a care giver and in the context of human evolution loud crying might attract predators. Crying has certain frequencies that are grating to adult ears. Crying expresses a need of the infant, but it seems that in a cooperative version of evolution these needs could be communicated with simpler, quieter signals. From weaning tantrums in primates to the loud begging of fledgling birds, parent-offspring communication often seems to reflect conflict rather than cooperation.

In 1974 Robert Trivers proposed an evolutionary framework within which to understand this conflict. Trivers' idea is rooted in the concept of kin selection. In this view, the evolutionary consequence of a behavior is affected not just by its impacts on the reproductive success of the actor, but also by the behavior's effects on the reproductive success of individuals sharing genes by common descent with the actor.

In the context of genetically monogamous family, a parent has a 50 % chance of sharing a given gene with an offspring and reciprocally an offspring has a 50 % chance of sharing any given gene with a parent. (Notated as a "degree of relatedness" of 0.5) Offspring (full sibs) are related to one another also by 50 %. A parent is equally related to all of his or her children. However, an offspring devalues benefits to siblings over benefits to itself. (It is perfectly related to itself but only 50 % related to a sibling). A parent's reproductive success is maximized if it feeds all offspring equally, but each offspring benefits from taking more than its share of the resources on offer. The conflict is usually seen when there are two or more competing siblings. However, the conflict exists if only one offspring is present. In this case, the parent is providing investment in relation to his or her lifetime reproductive effort, while the offspring devalues future offspring over its own benefits.

Benefits and costs are defined in terms of parental investment. Parental investment was defined by Trivers in 1972 as actions that increased the reproductive success of an offspring at the cost to the parent of producing future offspring. There can be an important difference between parental investment and the more general term parental care defined as any action directed at offspring that appears to benefit it. In the context of parent-offspring conflict, when food is abundant the offspring may not get any more benefit even with extra food being provided.

The differences in the degrees of relatedness in the family produce the conflict but at the same time constrains it. In true monogamy, an offspring is related to both parents by 0.5. It does not pay for an offspring to inflict costs on its parents greater than twice the benefit it receives. (Brood parasites, e.g., cuckoos are an exception where the chick is unrelated to the parents.)

The Status of the Theory

Some early critics argued that the parents were always in a position to impose their preference and conflict would not be seen. However, Trivers had already anticipated this idea and emphasized that offspring would be likely to be more likely to use psychological tactics, e.g., annoying crying than force. In the 1970s in a series of papers, Parker provided mathematical genetic underpinnings of the theory. More recently heritable genetic variation in begging behavior has been found in several species (e.g., Dor and Lotem 2009).

In 1995 Godfray produced an important modification to the theory. He argued that if begging (or any solicitation) is costly or risky to the offspring, there will come a point where the extra cost of solicitation will not be offset by the increased contributions of the parents. A costly signal becomes an honest signal. At this point, the offspring can no longer manipulate the parents and allocation of resources should follow the parents' optimum. The proposal requires solicitation to be costly. This has seldom been shown to be the case. The theory would also imply that offspring reach a stereotypical plateau of begging. However, there is evidence from several species that

begging animals alter their begging in relation to the target.

Parent-Offspring Conflict in Relation to Relatedness and Age

There are two variables that should vary with parent-offspring conflict, namely, the degree of relatedness within the family and parental age. With respect to degree of relatedness, Briskie et al. 1994 compared begging in species of bird where the female restricted her mating to her mate to species in which the female mated with several mates. In the latter case, young hatching in a brood may be half-siblings to one another. Begging was more intense in the less related broods. Boncoraglio et al. 2009 added eggs to the nests of barn swallows. Chicks in nests with unrelated eggs added begged more loudly than in normal nests. In humans, there are multiple studies showing that stepchildren (usually with a degree of relatedness of zero to the stepparent) are at greater risk of injury than natural children (Daly and Wilson 2007).

With respect to age, an older parent should hold back less for future offspring than a younger parent and should withhold little or nothing from the last child. There are a few results that show that older females invest more in their offspring. In red deer, older mothers give birth to calves in better physical condition, and the majority of human studies indicate that mothering improves with age (and this excludes the low level of maternal behavior seen in mothers under the age of 20). There are two problems studying the effects of age. First, senescence may reduce a female's ability to reproduce, and in most cases, an animal cannot know his or her chance of surviving to breed again.

For both relatedness and age, there is currently only spotty data in support parent-offspring conflict.

Who Wins Parent-Offspring Conflict?

It has proven very hard to collect data to determine whether parents or offspring are more likely to

distort benefits in their direction. The final fitness outcome of a relationship will be the sum of many individual interactions. In certain instances, e.g., when a mother chimp “gives in” and allows a screaming offspring access to the nipple, it appears that the offspring has its way. But integrating all such interactions has not been accomplished. (The only quantitative data on conflict resolution come from ants where Trivers and Hare (1976) could show that the conflict between the workers and the queen in a nest was usually resolved more in the workers favor).

David Haig (e.g., 1996) has analyzed examples of conflict over resources in pregnancy. Two medical conditions, preeclampsia and gestational diabetes, are probably the outcome of conflicts between the fetus attempting to garner resources and the mother countering. In the extreme but not unknown case of the mother dying from one of the two conditions, it seems clear that both parties in the conflict lose.

The Paradox

Our goal in this article was to illustrate how the theory [of parent-offspring conflict] can inform (and potentially revolutionize) both empirical and theoretical research. Schlomer et al. (2011)

We can certainly sympathize with these complaints having battled ourselves with designing empirical tests of parent-offspring conflict. Kilner and Hinde (2012)

These two quotes represent the paradox of parent-offspring studies. Schlomer et al. argue that parent-offspring conflict should be an important organizing principle for several branches of psychology notably all human developmental studies from infants onwards as well as topics such as mate choice particularly when parents and offspring differ. However, up to now only evolutionary psychologists have discussed the topic and then not very extensively.

Parent-offspring conflict is a powerful and interesting idea, but as the two excellent biologists from Cambridge lament, it has been very hard to go beyond the qualitative and produce good quantitative data.

Conclusion

Trivers theory of parent-offspring conflict provides a profound insight into family relationships. The biological interests of members of the family are not identical. Although supported by both theoretical and some empirical data, it has proven hard to collect good quantitative data on the topic.

Synonyms

[Intimate partner violence](#); [Uxoricide](#)

Definition

Partner abuse is a form of domestic violence where any cruel or violent action is directed against an intimate partner, sometimes resulting in homicide.

Introduction

Partner abuse refers to a form of domestic violence where any cruel or violent action is directed against an intimate partner, sometimes resulting in homicide. These actions include, but are not limited to, physical and emotional abuse, sexual assault, and manipulation, each of which poses serious physical or psychological harm to the victim. Data show that women are at a higher risk than men for being abused or killed by a current or former partner, and that in many cases they are repeat offenses (Browne 1993; Garcia-Moreno et al. 2005; Stockl et al. 2013). An extensive literature exists to understand the ultimate causes and proximate risk factors associated with partner abuse and homicide.

Theoretical Overview

Wilson and Daly (1992) argued that various forms of partner abuse and homicide stem from men’s proprietary view of their intimate partners. According to Trivers’ (1972) parental investment theory, when the sexes differ in their minimal obligatory parental investment (i.e., minimal resources needed to produce offspring), mating

strategies also differ. The sex with higher obligatory investment, typically females, can increase their reproductive success from a mate's genetic quality and from investing resources in offspring development and growth. The sex with lower obligatory investment can increase their reproductive success by increasing the number of mateships with the high-investing sex. Thus, there is a greater degree of competitiveness among males – those who are successful in acquiring a mating partner take a proprietary view of their partner due to the potential risks of losing her to competitors. This theoretical model predicts that men evolved traits that minimize or alleviate factors that jeopardize the stability and fidelity of this relationship. Since abusive actions by men may be adaptive, and are costly to women, sexual conflict theory may also help explain its causes and consequences (see ► [“Sexual Conflict”](#) entry). Daly and Wilson argued that partner abuse functions as *coercive control*, by preventing the probability of extra-pair mating, and that partner homicide is not adaptive but is a by product of conditions that cause proprietary actions. There should be a male-bias in the degree to which partner abuse is perpetrated, but this does not suggest women do not engage in partner abuse or homicide. Factors motivating either sex should be different.

Risk Factors

The conditions or traits that impact the stability and fidelity of an intimate relationship can be understood as risk factors associated with partner abuse or homicide. Sex, age, jealousy and cuckoldry risk, relationship status, and psychopathy are important risk factors because they are theoretically relevant and have been consistently linked with partner abuse and homicide.

Sex

Though variation exists across nations, most studies find that men are more likely to commit intimate partner homicide than are women (Dobash et al. 1992; Sabri et al. 2016). Data from the USA have been used to demonstrate equivalence

between the sexes on intimate partner homicide, but the USA seems to be an exception, and more recent research found that the US data are now more consistent with other nations (Sabri et al. 2016). Globally, two-thirds of all intimate partner homicide victims are women (United Nations Office of Drugs and Crime 2013).

When considering non-lethal partner abuse, sex differences are not as evident, where some studies find very similar rates of partner aggression by either sex, some even showing a slight bias towards women aggressors (Archer 2000). Although these findings highlight the importance of considering men's victimization, it is possible that methodologies used to acquire them exaggerate such effects (Dobash et al. 1992). For example, much of the data showing sexual symmetry comes from using a self-report measure, the Conflict Tactics Scale (CTS), which has questionable validity. Some CTS items that qualify someone as an abuser can also be interpreted in a non-aggressive way, and the measure inaccurately treats items as equally as severe. For example, *grabbing* and *slapping* are treated as “minor,” and *trying to hit* and *stabbing* are both considered “severe.”

Women are more likely to be identified as victims of partner abuse when other sources of information are used, such as injury data, police reports, emergency departments, and data from armed forces (Archer 2000; Dobash et al. 1992). Considering sexual symmetry or even higher rates of women abusing men seem to be true only in younger, dating, and student samples, it is possible that such effects are due to younger men inhibiting their aggression and do not react to female aggression to improve their chances of establishing a long-term relationship (Archer 2000).

Age

Wilson and Daly (1993a) hypothesized that younger women are at a greater risk of partner abuse because they have higher reproductive value, eliciting stronger competition and sexual jealousy. Younger women also have a higher likelihood of finding another spouse, giving men additional risk to losing partner. The data

supports this hypothesis – not only are younger women victimized more frequently abused by an intimate partner, younger women are more likely to have partners with higher levels of sexual jealousy (Serran and Firestone 2004).

An alternative explanation for young women being at higher risk is that they also happen to be in a relationship with younger men, a group known to be violent (Peters et al. 2002). Daly and Wilson ruled out this explanation by showing that spousal homicide is more likely to occur when the male partner is older than the female (Wilson et al. 1993). They hypothesized that increased risk with higher age disparity could be due to men feeling more threatened and jealous, having previous partners that cause greater conflict in the current relationship, or some other third variable associated with conflict and interest in much older or younger partners.

Jealousy and Cuckoldry Risk

Sexual jealousy and cuckoldry risk are leading factors associated with intimate partner physical and sexual violence, and spousal homicide (Buss and Shackelford 1997a; Camilleri and Stiver 2014). Men faced distinct consequences due to a partner's sexual infidelity, the most salient being paternity uncertainty of their offspring (Serran and Firestone 2004). Considering women are always certain their offspring are genetically related to them, only men are at risk of being cuckolded (i.e., unknowingly raising unrelated offspring). This situation would have posed a strong selection pressure on men to identify and minimize this risk. To prevent such consequences from occurring, men attempt to control their partners' reproductive capacities, resulting in the use of coercive tactics, such as the use of violence, in an attempt to regain control (Serran and Firestone 2004). Spousal homicide is suggested to be a nonadaptive, unusual manifestation of similar conflict (Serran and Firestone 2004; Wilson et al. 1995).

Intimate partner sexual violence is also associated with risk of infidelity from one's partner. It has been hypothesized that sexual coercion reduces the risk of cuckoldry by engaging in sperm competition. Much of the literature has

found a robust link between infidelity risk and partner-directed sexual coercion and rape (Camilleri and Quinsey 2009b; Goetz and Shackelford 2006).

Other sexually coercive actions that qualify as partner abuse may function to prevent opportunities for extra-pair copulations from happening. These actions include: *herding*, which is when men aggressively separate women from other men; *sequestration*, which is when men aggressively remove women from their social group; and *harassment*, which is when men persist in their sexual pursuit until the female relents or escapes. Each of these abusive actions may function to prevent extra-pair copulations.

Women Who Abuse Men

Women also engage partner abuse and homicide. The motivations, however, appear to be different from men's: (i.e. women typically murder their husband out of self-defense or defending their offspring (Wilson et al. 1993). Interestingly, women show higher rates of abuse in studies that use younger, dating, and student samples, whereas men show higher rates of abuse in studies that use older, marital/cohabiting, and community samples, possibly because men are less prone to being aggressive in a situation where it would be easier for the female to leave the relationship (Archer 2000).

It is also possible that because women are more prone to emotional jealousy than are men, (i.e. women can increase reproductive success through mate quality, which includes having a mate with resources and/or spends time helping raise offspring) it is possible that women's response to emotional infidelity, in which time and resources are directed towards another mate, might motivate them to behave in ways that would minimize this risk (Buss et al. 1992). Consistent with this view, women do engage in some mate retention actions when their partner has a larger income, such as responding to an infidelity threat with punishment (Buss and Shackelford 1997b). Stieglitz et al. (2012) also found in a forage-farmer sample that 50% of spousal arguments are over the men diverting resources outside that relationship. (This measure of diverting resources outside the

relationship, however, included actions unrelated to infidelity, such as drinking) It is therefore possible that both men and women may respond to infidelity with coercive actions, but their function is slightly different – for men, it is to prevent a partner's sexual infidelity, whereas for women, it is to prevent a partner's emotional infidelity. More data specifically testing hypotheses about these possible sex differences are needed.

Relationship Status

Spousal homicide against both wives and husbands occurred more frequently in *de facto* (cohabitating) relationships than in registered marital unions. However, the youngest wives have been found to be at greatest risk in registered marital relationships, whereas in *de facto* unions, risk was found to be greatest among middle-aged wives (Wilson et al. 1993). Poverty and young adulthood are both associated with higher homicide rates and *de facto* unions are generally more prevalent among the young and impoverished. *De facto* unions are also generally childless, which could lead to the increased likelihood of estrangement as women in dating relationships can terminate the relationship more easily than women in marital relationships. Childless relationships are indeed associated with higher spousal conflict and divorce in registered marital unions (Wilson et al. 1993). *De facto* unions are also more likely to include stepchildren, which is a risk factor for spousal conflict and violence.

Many studies have shown that sexual jealousy and estrangement have been a common motive for intimate partner violence and homicide committed by men (Capaldi et al. 2012; Wilson and Daly 1998). In fact, there seems to be an elevated risk of partner homicides when couples are no longer residing together, possibly because such a scenario clearly indicates loss of a partner, leading to more coercive actions. Not only has estrangement been found to be a risk factor for uxoricide, but sublethal assaults have also been found to increase when separated. Women who had previously suffered from spousal abuse prior to separation are more likely to experience serious abuse following separation (Wilson and Daly 1993b). Research has shown that in the first few months

following separation, risk levels are at their highest; however, it has also been found that spousal homicide can occur months or even years later (Wilson and Daly 1993b).

Psychopathy

Although little attention has been paid to the consequences of being in an intimate relationship with a psychopath, some research has found that partner-psychopathy is associated with both intimate partner sexual and physical violence (Camilleri and Quinsey 2009a; Hilton et al. 2001). Psychopaths have been described as an obligate life-history strategy that includes, among other traits, high mating effort and coercive sexuality. It is therefore possible that such sexually coercive and aggressive actions continue even in a committed relationship.

Conclusion

Many of the risk variables associated with partner abuse and homicide stem from men's proprietary view of their intimate partners. Younger women are at risk of victimization because their higher reproductive value inspires greater competition for them, leading to greater jealousy and conflict in the relationship. Men are more likely to engage in partner abuse as a form of coercive control, sometimes leading to homicide. Jealousy, cuckoldry risk, and psychopathy are associated with both physical and sexual violence in relationships. These items do not represent all factors that are associated with partner abuse and homicide but are theoretically relevant and empirically robust. See Capaldi et al. (2012) for a systematic review on factors associated with intimate partner violence.

Partner Abuse and Homicide: Victims and Perpetrators

Jennifer C. Fotopoulos, Kellie Bertolini and
Joseph A. Camilleri
Westfield State University, Westfield, MA, USA

Partner abuse is defined as physical, emotional, and/or psychological abuse that occurs between partners (Caman et al. 2017). Partners include spouses, ex-spouses, and individuals who are or have dated and include couples who live together

and couples who do not. In the United States, incidents of partner abuse are estimated to occur between 4.8 and 5.3 million times a year (Sheehan et al. 2015). Approximately half as many men as women are victims of partner abuse and homicide. In 2010, 82% of victims of partner abuse and homicide were women (Sheehan et al. 2015). Though there is some national variation in the degree to which there are sex differences in spousal abuse, there are more men than women who are perpetrators across all locations (Wilson and Daly 1992).

Victims of partner abuse and partner homicide have similar characteristics. Many of these victims have lower socioeconomic status and less education, and female victims are generally younger than male victims (Kirkland Gillespie and Reckdenwald 2017; Swatt and He 2006). African-Americans are approximately 2.5 times more likely than Caucasians and others to be victimized (Caman et al. 2017), and individuals who live in more rural areas are more likely to be victimized (Jennings and Piquero 2008). Rurality presents higher exposure to risk variables, such as isolation from neighbors, higher rates of poverty, and lower levels of education (Kirkland Gillespie and Reckdenwald 2017).

Explaining Characteristics of Perpetrators and Victims

Evolutionary psychology may help explain patterns of partner abuse perpetration and victimology. Generally, intimate partner violence may be functional for men by using coercion to control the reproductive options of their intimate partner (Wilson et al. 1995). Since men have lower minimal obligatory parental investment, they can increase reproductive success through mate number, creating high competition between men for access to mating partners and placing men who are in intimate relationships at risk of cuckoldry. Wilson and Daly (1998) suggested that intimate partner violence decreases the probability of cuckoldry or loss of a partner to a rival. This theoretical model explains why men are typically the perpetrators and younger women

are typically the victims because there is greater competition between men for women with higher reproductive value. This does not mean women do not aggress against their partners. Much of women's aggression toward men is in response to being abused (Wilson and Daly 1992). A potentially unique characteristic of intimate partner homicide is the presence of "May–December" marriages, where men are much older than their partner (Wilson et al. 1995), though it remains unclear why such a pattern exists.

Though many evolutionary theorists agree that nonfatal IPV may be adaptive, there is some debate about intimate partner homicide, where some proposed that it is a byproduct of male sexual proprietariness (i.e., a belief of ownership and entitlement over intimate partners). Such a proprietary view would have aided men, who can increase reproductive success through mate number, to prevent competition for access to one's mate through coercive control. Sometimes, the coercive actions are so severe that they result in death (see ► ["Partner Abuse"](#) and ["Byproduct Theory \(Daly and Wilson\)"](#) entry). An alternative explanation is that uxoricide is an adaptation, because in the context of infidelity, it removes a mating opportunity from a rival and prevents gaining the reputation of a cuckold (see ► [Spousal Abuse and Homicide: Byproduct Theory \(Daly and Wilson\)"](#) and ► [Spousal Abuse and Homicide: Evolved Homicide Module Theory \(Buss\) \[Spousal Homicide\]"](#)). This explanation is problematic, however, because it is not clear whether these benefits outweigh the costs of losing a partner, losing a caregiver of any current offspring, reputation of being a murderer, and risk of retribution from the victim's family.

Partner Death as Designed Outcome

Delphine Malard and Joseph A. Camilleri
Westfield State University, Westfield, MA, USA

Intimate partner violence is when a person uses physical or sexual violence, stalking, or psychological harm against an intimate partner (Center for Diseases and Control 2020), the most severe being homicide. Though there is some variation in the sex-ratio of perpetrators who kill an intimate partner. Across most regions, men to a large extent perpetrate intimate partner homicide more often than do women, with the USA being an exception (Wilson and Daly 1992). Female victims of homicide are disproportionately victimized by an intimate partner (39%) when compared to the proportion of male victims of homicide who were victimized by an intimate partner (6.28%). One of the first evolutionary explanations for this sex difference is that intimate partner homicide is a by-product of men's use of violence to coercively control their partner's mating options, thereby reducing the probability of cuckoldry (Wilson and Daly 1993). An alternative hypothesis suggests intimate partner homicide is an adaptation.

Duntley and Buss (2005, 2011) proposed Homicide Adaptation Theory, which suggests killing was advantageous for our ancestors because it provided solutions to problems of survival and reproduction. Homicide could function in different ways, such as using it to: remove a competitor who inflicts costs; get access to resources or protecting resources; or build a reputation to prevent being exploited. Applying this logic to intimate partner homicide, they proposed that homicide could be a response to partner infidelity to preserve one's status, because gaining a reputation of a cuckold may have repercussions in terms of being exploited by rivals or future mating partners. Such actions would also reduce a rival's reproductive benefits. These ideas are fully explored by Buss (2006), Duntley and Buss (2005, 2011), and Duntley (2015).

Research supporting these hypotheses come from data on intimate partner homicide, where many such cases involve sexual jealousy or infidelity (Shackelford et al. 2003; Wilson and Daly 1993), and from homicide fantasies where estrangement and partner infidelity are the most common reasons men give for having persistent thoughts of killing a partner (Buss 2006). Potential concerns with these lines of support is that associating homicide with jealousy and infidelity is consistent with both by-product and adaptation hypotheses, and homicide fantasies may not be a valid indicator of actual homicides. To identify which explanation is most accurate, researchers need to identify whether the possible fitness benefits of intimate partner homicide outweighs the various costs. These costs include loss of a mating partner, familial retribution, loss of a caregiver to one's offspring, and gaining a reputation of a murder which may scare off future mates.

Though men account for many intimate partner homicides, some women also kill their intimate partners. There is evidence to suggest that rather than being the aggressor, women kill in response to being abused or victimized by their intimate partner. Research on women who kill their intimate partners requires much more theoretical and empirical attention.

Partner Desertion

[Mate desertion](#)

Definition

Partner desertion occurs when one member of a mated pair absconds, leaving the remaining partner to care for any offspring alone.

Introduction

In systems with biparental care, parents are caught in a cooperative dilemma. Each partner could potentially benefit by deserting its mate and their young to begin a new breeding attempt with a different partner or to conserve energy for future reproduction, if the deserted partner rears the young alone. However, the costs of desertion can outweigh potential benefits if a deserted partner is incapable of raising young successfully alone, is itself likely to desert the young, or is selected to incompletely compensate for the loss of the partner's care (Trivers 1972; Dawkins 1976; Lazarus

1990). A variety of factors can influence whether a breeding individual gains fitness benefits from deserting its mate, and many questions remain about how these factors interact as well as which are most important in driving desertion in systems with multiple factors at play.

Theoretical models have identified several factors that can lead to either high benefits or low costs of desertion, favoring the expression of desertion behavior. The benefits of desertion can be high when, for example, the sex ratio is strongly biased, the deserting sex experiences higher mortality than the caring sex, or sexual selection is strong (Grafen and Sibly 1978; Queller 1997; Kokko and Jennions 2008; Alonzo 2012). All of these factors influence the benefits of desertion by influencing the likelihood that a deserting individual can find a new mate to initiate a new breeding attempt. If the adult sex ratio is biased, a deserting individual belonging to the rarer sex is expected to easily find a new mate, while the deserted partner is unlikely to find a new mate if it also abandons the offspring and thus is likely to remain and care for the offspring (Grafen and Sibly 1978; Queller 1997; Kokko and Jennions 2008). If the deserting sex suffers mortality at a rate significantly higher than the caring sex, desertion is (counter-intuitively) favored, because the deserting sex becomes the rare sex and thus deserters are likely to find new mates (Kokko and Jennions 2008). If sexual selection is strong, a high level of competition between members of one sex for mates implies that any individual of that sex who has a mate is a successful competitor, and thus is likely to succeed in gaining a second mate if it deserts its partner (Queller 1997; Kokko and Jennions 2008). However, this relationship can also be reversed, such that sexual selection disfavors desertion, if the target of mate choice by the choosy sex is investment in parental care (Alonzo 2012; Kokko and Jennions 2008), or if providing care yields greater fitness benefits than re-engaging in competition for a new mate (Kokko and Jennions 2008).

Factors that influence the costs of desertion often mediate the extent to which a single parent can successfully rear young alone. For example,

the costs of desertion may be reduced when food is abundant, as a single partner can feasibly collect enough food to provision the young (Emlen and Oring 1977). The costs of desertion can also be reduced by multiple mating: if one sex consistently has lower mean relatedness to its putative offspring, the sex with lower mean relatedness suffers a lower fitness cost of deserting that brood than does the sex with higher mean relatedness (Trivers 1972; Queller 1997). Another scenario in which the costs of desertion can be reduced is when partners are unspecialized in their care tasks, because each partner can perform all of the care necessary to raise offspring to independence: stable biparental care, without partner desertion, is more likely when males and females specialize on different care tasks than when carers are unspecialized (Grafen and Sibly 1978; Kokko and Johnstone 2002; Barta et al. 2014).

When comparing empirical evidence with theoretical models of partner desertion, it is important to remember that evolutionary models often make predictions that are testable with cross-species but not within-species comparisons (Kokko and Jennions 2008). For example, the prediction that the sex with lower mean relatedness to the offspring will be more likely to desert (Queller 1997) implies that species in which males have lower mean relatedness to offspring than do females will have a higher rate of male desertion than female desertion; the prediction does not imply that males will respond flexibly to their partners' extrapair mating by deserting offspring when their partners mate multiply. Socially monogamous birds show wide variation in partner desertion behavior, presenting opportunities for cross-species studies. While desertion by both males and females occurs in several species, female-only desertion is less common (Morton et al. 2010). Female desertion often occurs during the late nestling or postfledging care period (Tindle 1984; Wiktander et al. 2000; Griggio and Pilastro 2007; Szentirmai et al. 2007; Morton et al. 2010; Korpimäki et al. 2011); a factor contributing to this pattern may be that care necessary for early offspring development (e.g., incubating eggs and brooding young nestlings) is often provided primarily by females,

while the food required by older nestlings is provided by both males and females (Korpimäki et al. 2011). Although task specialization is beginning to be considered in models (Barta et al. 2014), specialization on care during certain developmental stages is not; incorporating this timing specialization into models could provide a stronger link between partner desertion theory and empirical results.

Conclusion

Two important future goals for research on partner desertion are comparing biparental and cooperative care systems, and the development of models that simultaneously examine multiple factors predicted to influence the fitness consequences of partner desertion. The first goal is important because, while the majority of partner desertion research to date has focused on systems in which care is provided solely by parents, the additional offspring care provided by at least one nonparent in cooperatively breeding systems has the potential to alter the fitness consequences of partner desertion. Models of the influence of nonparent carers on the likelihood of partner desertion are largely lacking, although several studies have investigated how carers respond to changes in each others' investments in care in multicarer systems (Härdling et al. 2003; Johnstone 2011; Savage et al. 2013). Both theoretical and empirical work on the characteristics of cooperative species in which partner desertion occurs are needed to understand how the conditions leading to partner desertion differ between biparental and cooperative care systems. The second goal, the development of models that incorporate multiple factors that can influence partner desertion, is crucial in order to determine the relative importance of different factors in predicting desertion behavior (Kokko and Jennions 2008). Recent examples of the power of this approach include work by Barta et al. (2014) showing that task specialization can prevent desertion even when sexual selection is strong, and by Alonzo (2012) showing that female choice for parental males can reduce male desertion even when mean relatedness between males and the offspring for which they provide care is low due to multiple mating. More investigations of the

interactions between factors are needed, both to resolve theoretical questions about which factors most strongly influence selection pressures and to derive empirically testable predictions.

Partner Homicide

Vibeke Ottesen

Department of Bioscience, Centre for Ecological and Evolutionary Synthesis (CEES),
University of Oslo, Oslo, Norway

Synonyms

Femicide; Intimate partner homicide; Mariticide;
Uxoricide; Wife killing

Definition

Partner homicide, also listed in the scholarly literature as intimate partner homicide, refers to homicides where the victim and perpetrator are, or have previously been, in an intimate (romantic/sexual) relationship.

Introduction

Unlike most other homicide categories, the vast majority of victims of partner homicide are women. According to a report on the epidemiology of homicide worldwide, published by the United Nations Office on Drugs and Crime (2019), roughly 82% of the victims of partner homicide are women. This global sex difference in the rate of victimization has been stable since 2012. However, the specific rates at which the two sexes are victimized differ between societies. For instance, the victimization rate is four times higher for women than for men in Europe, and in Latin America, the rate is five times higher for women than for men. In contrast, the victimization rates for women and men in the USA have been remarkably even. For instance, for every 100 women killed by their husbands in the USA in the years 1976–1985, about 75 men were killed by their wives (Wilson and Daly 1992).

Although the victimization rates differ between societies, the characteristic traits of the perpetrators, victims, and circumstances of partner homicides appear to be cross-cultural. The cross-cultural similarities in characteristic traits of partner homicides undermine the notion that these homicides are solely driven by cultural norms or are random acts of individuals suffering some form of mental pathology. Rather, as will be detailed in the following, the cross-national similarities lend themselves to supporting the evolutionary psychological hypothesis that partner homicide is a behavioral manifestation of evolved psychological mechanisms that are triggered in the context of reproductive conflicts.

Hypothesis: Reproductive Conflicts Are at the Core of Partner Homicides

Evolutionary psychologists Martin Daly and Margo Wilson (1988) proposed that homicides, including partner homicides, should be understood as assays to reproductive conflicts. A reproductive conflict occurs when individuals have differing interests pertaining to their respective reproductive success, and the interests of one individual come at a cost to another individual. Daly and Wilson proposed that there are evolved psychological mechanisms that are triggered when individuals are confronted with reproductive conflicts. These psychological mechanisms have enabled the individual to react to the given conflict in ways that, on average, were beneficial toward reproduction or survival in our species' past. These mechanisms may elicit a range of behavioral responses, including lethal violence. According to Daly and Wilson, these psychological mechanisms are adaptations, the products of evolutionary selection processes. The range of potential behavioral outputs that may be performed on the basis of these mechanisms are then by-products. Thus they argued that adaptation must be sought at a psychological rather than behavioral level when studying homicide perpetration. They further argued that of the range of potential behavioral manifestations of the evolved psychological mechanisms that are triggered in the context of reproductive conflicts between intimate partners, homicide perpetration is an extreme and dysfunctional epiphenomenon, as it would not benefit the individual in any evolutionary significant way to perform such an act.

Evolutionary psychologists Joshua Duntley and David Buss (2008, 2011) have a somewhat different take on the benefits of homicide perpetration. They argue that the benefits of homicide perpetration, including partner homicide, were so significant to the individual in our evolutionary past that psychological mechanisms with the specific function of eliciting homicidal behaviors would have been selected for. What these two different perspectives have in common is the hypothesis that partner homicides occur in the context of reproductive conflicts.

Predicted Traits of Partner Homicide and Their Empirical Support

From their hypothesis that partner homicides occur in the context of reproductive conflicts within the couple, Daly and Wilson (1988) derived a list of risk factors for partner homicide – traits that they predicted would be characteristic for the perpetrators, victims, and circumstances for partner homicide, if their hypothesis were valid. This list, and the cross-cultural empirical support for them, will be detailed in the following.

Sex Differentiation in Motive for Partner Homicide Perpetration

The initiation and maintenance of long-term, intimate relationships is assumed to have had the evolutionary function of framing collaborations in fostering genetically shared children. Daly and Wilson (1988) proposed that the profoundly different physiological roles women and men have in reproduction would lead to sex-differentiated concerns regarding threats to this collaboration. These threats could be perceived as reproductive conflicts within the given couple. Daly and Wilson suggested that because the two sexes have such different physiological roles in reproduction, evolution would inevitably shape sex-differentiated psychological mechanisms for assessing cues for and acting on reproductive conflicts in intimate relationships. From this evolutionary informed reasoning, they predicted a list of characteristic traits for partner homicide perpetrated by women and men, respectively.

Sexual Proprietariness

A sex-specific reproductive challenge to ancestral men was the potential uncertainty as to whether or not a child in their care was their genetic offspring. This lack of certainty made them vulnerable to being cuckolded by a partner (i.e., unknowingly investing in the fostering of another man's offspring). Selection would favor men with psychological mechanisms that could protect against cuckoldry, as such mechanisms could increase the likelihood of that the individual man invested in his own genetic offspring, and not the offspring of his – in evolutionary

terms – competitors. Psychological mechanisms that would potentially protect against cuckoldry could be ones that made the individual man sensitive to cues of his partners' sexual infidelity, and that motivated him to take measures to reduce the likelihood of such infidelity. Men with such mechanisms could potentially outreproduce those men who did not have a sensitivity toward cues of and a concern with the sexual fidelity of their partners.

Daly and Wilson (1988) proposed that this male sensitivity to cues of and concern with the sexual infidelity of a partner could be described as underpinning a sexual proprietariness. This concept refers to a mind-set encompassing a presumption of ownership of and entitlement to an exclusive sexual access to a partner. This mind-set may motivate an inclination to exercise control over a partner's reproduction and reproductive options and taking measures to prevent losing that control. A range of behaviors may serve the function of preventing a partner from pursuing reproductive opportunities with other people (Buss and Shackelford 1997). Daly and Wilson noted that violence is among the effective behaviors a man could engage in to deter a partner from pursuing reproductive opportunities with other men and constraining her reproductive options to align with his interests. And at times, as a rare and extreme manifestation of the proposed evolved proprietary mind-set, the man might resort to lethal violence.

Daly and Wilson (1988) therefore predicted that male-perpetrated partner homicide would characteristically occur when the man experienced threats to an exclusive sexual access to his partner, such as in the context of suspected or actual adultery or the partner initiating a termination of their relationship.

There is empirical support for this prediction, as sexual jealousy and female-initiated relationship dissolution are the context in which male-perpetrated partner homicides most frequently occur. For instance, in a Canadian national sample, 1974–1983, 25.5% of the homicides perpetrated by husbands were after police investigations attributed to jealousy, whereas only 7.9% of those perpetrated by wives were

attributed to jealousy (Daly and Wilson 1988). This finding was replicated in a sample extending to 1990 (Wilson and Daly 1993) and in a local Canadian sample, from the city of Hamilton, 1974–1995, where male-perpetrated partner homicide characteristically occurred soon after the women initiated separation (Daly et al. 1997). Also in a sample from New South Wales, Australia, 1968–1986, and a Chicago sample, 1965–1990, the risk for female victimization was substantially elevated when the couples were estranged than when they were co-residing (Wilson and Daly 1993). Specifically, the risk of being killed was six times higher for women estranged from their husband than for women still living with their husband. In the Australian sample, about half the women were killed within 2 months of leaving their husband, and 91% were killed within a year. The data from the Chicago sample suggested that the male perpetrators were distressed at their victims initiating the dissolution of their relationship or having the intent to leave. In notable contrast, the risk for male victimization appeared to be considerably lowered in estranged couples.

Staying Alive

Evolutionary psychologist Anne Campbell (1999) noted that for ancestral women, staying alive was one of the more crucial requirements for reproductive success. Unlike men, who have no physiological obligation beyond their participation in conception, ancestral women were compelled to stay alive throughout the lengthy period of gestation and years of breastfeeding in order to achieve reproductive success. Campbell argued that this sex-differentiated selection pressure to stay alive has shaped a female psychology that motivates an avoidance of physical danger. Daly and Wilson (1988) also noted this crucial sex difference in the reproductive requirement to avoid physical danger and proposed that for a woman to nevertheless engage in the act of partner homicide, an act that might potentially be lethal to herself if her partner was to fend off her attack, her motivation had to be that her partner already endangered her survival. They therefore predicted that women who kill a current or former partner

would do so in the context of ensuring their own survival.

There are fewer studies on female than male-perpetrated partner homicides and fewer still that collect data on motives. However, existing studies collectively give empirical support to Daly and Wilson's prediction, as a majority of female-perpetrated partner homicides are reportedly motivated by self-defense (for a review of the empirical literature, see Campbell et al. 2007). For instance, in a sample from Denver in the USA, 1991–2009, the male victims of partner homicide had prior domestic violence arrests three times more often than female victims of partner homicide (Belknap et al. 2012). This sex difference increased to more than seven times for domestic violence convictions. Data on the motive for female-perpetrated partner homicides was available for only 12 cases in the sample. Of these, five perpetrators clearly killed their partner in self-defense. In two cases it was more complicated: Although there were elements suggesting the relationship had been “mutually combative,” the female perpetrators had records showing prior domestic violence victimization at the hands of their partners. Belknap and colleagues note, with surprise, that three cases were most consistent with being an artifact of the women acting on a sexual proprietariness. The last two cases were not categorized.

Age of Perpetrator and Victim

If the reproductive conflict that lies at the core of male-perpetrated partner homicide is one concerning the man losing his partner as a contributor to his fitness, the severity of his reaction to this loss may be expected to be dependent on his partner's fecundity (i.e., ability to produce offspring). Daly and Wilson (1988) therefore proposed that the age of the woman, which is a proxy for her residual fecundity, might have a significant impact on the man's response to losing her as a contributor to his fitness. The woman's age may therefore be a better predictor for the risk of partner homicide than the man's age (a man's age is otherwise a well-established predictor for the risk for homicide perpetration, as young men are overrepresented among perpetrators; see, e.g.,

the United Nations Office on Drugs and Crime 2019). This reasoning led to three predictions concerning age and the risk for partner homicide.

The Woman's Age as a Predictor for the Risk for Victimization

From the above reasoning, Daly and Wilson predicted that an increase in the woman's age would be associated with a decrease in her risk for partner homicide victimization. The empirical evidence supports their prediction. For instance, in a Canadian national sample, 1974–1983, the risk for partner homicide did indeed decrease with an increase of the woman's age for married couples (Daly and Wilson 1988). This finding was replicated in a sample extending to 1992 (Wilson et al. 1995b). In a US local sample from the city of Chicago, 1965–1996, 82.8% of the female victims were < 45 years old (Breitman et al. 2004).

However, the association between the woman's age and risk for partner homicide victimization appears to be dependent on the type of union the couple have. For cohabiting women, the risk for victimization increases until they are middle-aged, before dropping. This was identified in a Canadian national sample, 1974–1983 (Daly and Wilson 1988), and replicated in a sample extending to 1992 (Wilson et al. 1995a), and in US national samples for the years 1976–1994 (Shackelford and Mouzos 2005) and 1990–2005 (James and Daly 2012). However, this age difference in risk for victimization associated with type of union was not replicated in an Australian national sample, 1989–2002, where cohabiting women were, similarly to married women, at greatest risk when they were < 25 years old (Shackelford and Mouzos 2005).

Daly and Wilson (1988) suggested that the difference between married and cohabiting women in their apparently age-related risk for partner homicide victimization might be an artifact that cohabiting couples have children from previous relationships more frequently than married couples and that the likelihood of having children from previous relationships increases with the age of the woman. And, as will be returned to, having children from previous

relationships has been identified as a factor that increases the risk for female victimization.

The Woman's Age as a Predictor for the Risk for Perpetration

As the man may engage in more vigilant and coercive control, even to the extent of lethal violence, toward a young partner, Daly and Wilson (1988) predicted that a woman's young age would be associated with an increased risk for female-perpetrated partner homicide, as the woman reacts to her partner's threatening behavior (see section "[Staying Alive](#)" of this entry, concerning women's motivation for perpetrating partner homicide as self-defense). The empirical evidence supports their prediction, as a woman's young age does in fact increase the risk for male victimization. This was found in the Canadian national sample, 1974–1983 (Daly and Wilson 1988). In a Chicago sample, 1965–1996, women <45 years old constituted 82.9% of the female perpetrators (Breitman et al. 2004). Also in a US national sample, 1976–1994, and an Australian national sample, 1989–2000, of married perpetrators, the risk was highest for younger women (<25) and decreased with age (Mouzos and Shackelford 2004). For cohabiting women, however, the risk for perpetration peaked at a later age in both samples.

Age Disparity as a Predictor for the Risk to Both Sexes

It could be argued that more than a woman's absolute age, her age relative to her partner is a better proxy for her value to him as a contributor to his reproduction and thus a better predictor of risk for reproductive conflicts and partner homicide. Empirical evidence supports the prediction, and further the excess risk for victimization appears to be to the older individual in the couple, regardless of sex. For instance, Daly and Wilson (1988) found in a Canadian national sample, 1974–1983, that there was an increased risk for both female- and male-perpetrated partner homicide with increased age disparity. Further, a greater age disparity increased the risk regardless of what type of relationship the couples were in. These findings were replicated in a sample

extending to 1992 (Wilson et al. 1995), a national sample from England and Wales, 1977–1986 (Wilson and Daly 1992), a Scottish national sample, 1978–1987 (Wilson and Daly 1992); Australian national samples of female perpetrators, 1989–2000 (Mouzos and Shackelford 2004), and male perpetrators, 1989–2002 (Shackelford and Mouzos 2005); a regional sample from New South Wales in Australia, 1968–1986 (Wilson and Daly 1992); a US national sample, 1976–1994 (Mouzos and Shackelford 2004; Shackelford and Mouzos 2005); and a local US sample from the city of Detroit for the year 1972 (Wilson and Daly 1992).

Replicating the above-listed findings in a sample of partner homicides in Chicago, 1965–1996, Breitman et al. (2004) specifically identified that when the woman was older than her partner by 16 years or more, the rate of partner homicide was four times higher than for couples with no age difference. When the man was 16–20 years older than his partner, the rate of partner homicide was four and a half times higher than for couples with no age difference. The highest risk for partner homicide in this sample was for couples where the woman was 10 years older than her partner and for couples where the man was at least 16 years older than his partner. The perpetrator was older than the victim in near half of the incidents in the sample.

There has not yet been formulated an evolutionary informed reasoning and prediction concerning the increased risk for partner homicide in couples where the male is the younger party. But in line with the hypothesis that partner homicide occurs in the context of reproductive conflict, one may identify potential sources for such conflicts also in these couples. For instance, the young age of the man may be a proxy for the increased potential for him to produce healthy offspring (also see "sexy son theory"), which may be a significant reproductive cue for his partner. Also, an older woman might be a resourceful provider for a young man. The age disparity in these couples may then be a proxy for a disparity in mate value, which in turn could increase the vigilance and coercion with which the individual with the lower mate value reacts

to a potential loss of their partner as a contributor toward their own fitness.

Increased Risk Among Cohabiting Couples Compared to Married Couples

Cohabiting couples have a significantly increased risk for partner homicide compared to married couples. For instance, in a Canadian national sample, 1974–1983, cohabitating couples had an increased risk for both male and female victimization (Daly and Wilson 1988; Wilson and Daly 1992). This finding was replicated in a sample extending to 1992, where the rate of partner homicide was about eight times higher among cohabiting couples than among married couples (Wilson et al. 1995; see also Wilson et al. 1993). This finding has been replicated in England and Wales, 1977–1986 (Wilson and Daly 1992); the USA, 1976–1994 (Mouzos and Shackelford 2004; Shackelford and Mouzos 2005); Australia, 1989–2000 and 1989–2002 (Mouzos and Shackelford 2004; Shackelford and Mouzos 2005); and a local Australian sample from New South Wales, 1968–1986 (Wilson and Daly 1992).

Daly and Wilson had not sketched out any evolutionary informed reasoning and prediction concerning differentiated risk associated with type of relationship prior to identifying the increased risk for partner homicide among cohabiting couples compared to married couples. Upon discovering this characteristic trait for partner homicide, Daly and Wilson suggested that the increased risk might be an artifact of that commitment, and thus investment, is lower for cohabiting than married couples, and further considered whether cohabiting couples were more often poor, young, city dwellers. Such circumstances, they suggested, may in turn spur a more vigilant and coercive proprietariness in the relationship, and in turn this may lead to lethal violence.

However, findings from a US national sample, 1990–2005, have shown that cohabitation is not a static risk factor for partner homicide (James and Daly 2012). The respective rates of partner homicide among cohabiting and married couples converged over this time period in the USA, and by 2005 the risk was equal between the two types

of union. This change in risk occurred despite differences in demographic characteristics associated with married and cohabiting couples with regard to age distribution, and unemployment rates remained the same, and differences in level of education and income increased.

Children from Previous Relationships

In stepparental households the couples do not share the profound reproductive interest in investing in the children, as the couples do in households with two genetic parents. If the genetic parent wants more investment in the child than the stepparent is volunteering, this is a reproductive conflict that may be a major source of discord for the couple. Daly and Wilson (1988) therefore predicted that because of the increased potential for reproductive conflict with regard to the level of parental investment in stepparental households, such households might have an increased risk for partner homicide.

There is empirical evidence that supports their prediction. For instance, in a local Canadian sample from the city Hamilton, 1974–1995, the rates of partner homicide with female victims were substantially elevated in stepfather families (Daly et al. 1997). Half of the victimized mothers in the sample had children from previous relationships, compared to 7% of the population at large. Their risk for partner homicide victimization was thus 12.7 times higher than for women living in households with two genetic parents.

Familicide

Familicide is the killing of one or more children in addition to a current or former partner. From the same evolutionary informed reasoning as sketched out so far, it has been predicted that familicides will predominantly be perpetrated by men and occur in the context of the woman initiating a dissolution of the relationship (Wilson et al. 1995). There is empirical support for these two predictions. For instance, 93% of familicides in Canada, 1974–1990, and 96% of familicides in the UK, 1977–1990, had male perpetrators (Wilson et al. 1995). The available data also suggests that the familicides were elicited by the relationship dissolution initiated by the women.

Thus the victimized children do not appear to be the primary objects targeted by the perpetrators. Further, familicides appear to be more similar to partner homicide than child homicide with regard to perpetrators age, method of killing, and victim's age (Wilson and Daly 1992; Wilson et al. 1995a) and may therefore arguably be listed as a subcategory of partner homicide rather than a subcategory of child homicide (filicide).

Nonheterosexual Relationships and Partner Homicide

Both conventional social science and evolutionary psychological perspectives have given less theoretical and empirical attention to partner homicides in nonheterosexual relationships. However, some works that reference evolutionary psychological perspectives may form a foundation for a theoretical understanding of the underpinning psychology and thus improve identification of risk factors for partner homicide in nonheterosexual relationships. For instance, a study using a US national sample, 1976–2001, explored the methods and rates of partner homicide among heterosexual, gay, and lesbian relationships (Mize and Shackelford 2008). And a study using a sample from the Metropolitan Area of Buenos Aires City in Argentina (Aristegui et al. 2019) explored how transgendered people respond when confronted with romantic rivals. Assuming such confrontations will trigger psychological mechanisms evolved to detect and react to reproductive conflicts, such studies may be crucial to identifying the underpinning psychology and deriving predictions concerning characteristic traits of homicide perpetration among transgendered couples.

Cross-National Variance in Rates of Partner Homicide

In contrast to perspectives claiming that partner homicide is a product of, for instance, culturally driven gender roles or random acts caused by the perpetrators' psychopathology, evolutionary psychological perspectives argue that the psychological mechanisms underpinning the perpetration

of partner homicide are evolved adaptations, and as such are shared commonalities in our species. The variance that exists between and within nations in the extent to which partner homicide is perpetrated does not undermine the notion that the underpinning psychological mechanisms are species-typical. As with other evolved psychological mechanisms, the activation of mechanisms that may elicit lethal violence against a current or former partner is context dependent. And, further, the range of behavioral manifestations of the mechanisms is not limited lethal violence. Although Duntley and Buss (2008, 2011) argued that there are psychological mechanisms that specifically activate partner homicide, they also argued that the activation of these mechanisms is context dependent.

From an evolutionary psychological perspective, the variance in rates of partner homicide between and within societies is therefore expected to be largely attributable to the variance individuals in the given societies are exposed to the social factors and contexts that activate the relevant underpinning psychological mechanisms, and further what behavioral outlets are available for the manifestation of the mechanisms in the respective societies.

If this evolutionary psychological perspective on partner homicide is valid, variations within and between societies in the extent to which partner homicide is perpetrated should be predictable. So far the research performed with reference to this theoretical framework has emphasized identifying the commonalities in the patterns of characteristic traits of partner homicide across nations and cultures, rather than exploring the predictability of unique patterns in characteristic traits in a given society or culture (for one exception, see Daly and Wilson's (1992) study of the evenness in perpetration rates for women and men in the USA). The range of cultures where partner homicide has been studied from an evolutionary psychological perspective have been limited to Canada, the USA, the UK, and Australia. Future research would benefit from adding nations and cultures to this list to explore the robustness of the findings produced so far within this theoretical framework, by testing the predictive power of the framework

in non-Anglo nations and societies and the notion of partner homicide perpetration being contingent on environmental cues.

Conclusion

Benefitting from the theoretical guidance offered by an evolutionary informed understanding of how selection processes form social behaviors, evolutionary psychologists have derived the hypothesis that homicides, including partner homicides, are triggered by reproductive conflicts. From this hypothesis, they have been able to identify a list of characteristic traits of partner homicide – some of which were not identified by contemporary conventional approaches to studying partner homicide, such as the increased risk for couples with co-residing stepchildren and for couples with a significant age disparity.

Crucial to predicting what traits will be characteristic for partner homicides is the recognition of how profoundly different the physiological roles of women and men are in reproduction. This recognition entails appreciating that the respective physiological roles of women and men in reproduction give equally sex-differentiated challenges to reproductive success and that this in turn will inevitably spur the evolution of sex-differentiated cues to reproductive conflicts with an intimate partner and sex-differentiated ways of handling these conflicts. For men, the greatest concern would arguably be securing genetic paternity, whereas for women it would be to stay alive. The empirical support gained for the predictions derived from the hypothesis that reproductive conflicts lie at the core of partner homicide perpetration for over four decades testifies to the validity of the hypothesis.

The merits of the evolutionary psychological hypothesis that reproductive conflict lies at the core of homicides are not limited to explaining and predicting significant risk factors and characteristic traits of partner homicide. It has also proven its validity for other homicide categories, such as filicide (killing of a child by a caretaker), siblicide (the killing of a sibling), and parricide

(the killing of a parent) (for an introduction, see Daly and Wilson 1988). This makes evolutionary psychology singular among the theoretical perspectives within the scientific field of homicide studies as it succeeds in approaching the phenomenon in a comprehensive manner to both explain and predict a list of characteristic traits for a diverse list of homicide categories.

Definition

Partner Killing – When one commits the act of killing their partner of whom they have a consensual relationship in the form of intimate, romantic, or sexual context. Partners may be identified within the following relationships: marriage, committed relationship (cohabitating and non-cohabitating), casual dating, “friends with benefits,” or strict sexual partners. Throughout this chapter, we will be discussing the topic of intimate partner killings (IPK) using the term “Paricide(s).” This term is not yet standardized but was derived from the root origins of “Partner-Par” and “Killing-Cide.” Related terms include Femicide – “deliberate killing of women and girls because they are female” (Campbell 2018); Matricide – killing of one’s mother (Heide 2013); Uxoricide – killing of wife by husband (Mize et al. 2011).

Introduction

This chapter aims to tackle the topic of intimate partner killings (IPK) and provide a comprehensive overview of the literature and research up to date. We will also be looking at many variables that have been discussed throughout different forms of literature and linking them together. Several of these variables include the timelines, national databases available, partner types, relationship types, relationship status, age discrepancies, location most likely to occur, and type of weapons used. Lastly, we will look at corollary victims, demographic data, motivation for killings, personality traits, neurological factors, evolutionary factors, and previous history data for intimate partner violence.

The Evolution of Paricide

Paricide is an act seen often in history due to motivations often driven by intense emotions, whether that be rage, jealousy, or fear (Mize et al. 2009). Dating back to the era of Cleopatra in 41 B.C., she was known for killing her husbands as a means to gain power or the upper hand in war (Andrews 2019). Another famous

historical figure that participated in paricide includes Queen Isabella, known as the “She-Wolf of France,” who executed her husband, motivated by revenge due to her husband’s affairs. In addition, Catherine the Great threw her husband in jail for execution due to the issues of power and relationship conflict (Meares 2017).

Considering Darwin’s sexual selection theory, Douglass et al. (2020) suggest, “The essence of Darwin’s theory of sexual selection pits males and females in competition, with each other (intersexual competition) and with themselves (intrasexual competition), in a way that is believed to have far-reaching consequences in how each sex has evolved.” Also, Baumeister et al. (2001), Ellis and Symons (1990), Jonason and Fisher (2009), and Mitchell et al. (2018) indicate men have evolved a stronger libido, various sexual partners, and desires for short-term mating. Douglass et al. (2020) acknowledge that these evolved attitudes lead to emotions such as jealousy, need for power, and control among female partners. Evolutionary explanations have also suggested intimidate partner violence as a defense mechanism when avoiding paternal uncertainty (Daly et al. 1982). Furthermore, explanations for females acting out aggressively are linked to scarcity of resources (Campbell 2015; Campbell et al. 1998), response to infidelity (de Weerth and Kalma 1993), competition for survival, and protection of offspring (Douglass et al. 2020).

Paricide Prevalence

This phenomenon is not isolated but a global issue across all countries as one in seven homicides and more than a third of female-related homicides are committed by an intimate partner (Stöckl et al. 2013). Shown below are more global statistics found by Stöckl and colleague (2013) (Table 1):

Adolescent Dating Violence as a Risk Factor

According to Knopf (2019), 7% of teen homicides are related to partner killing, and these killings are

typically a result of jealousy or breakups. Partner killings in teens typically involve gun violence and are femicide related (Knopf 2019). When exposed to maladaptive relationship patterns in adolescence, these patterns are likely to carry out into adulthood. Patriarchal culture holds views related to favoring violent behaviors in boys as a means of compensating when their virilities are threatened (Taquette and Monteiro 2019). Gender inequality is another risk factor among females within the adolescent population, yet there are instances where women are more likely to be physical and psychological aggressors as a result of developmental stage and hormonal changes (Taquette and Monteiro 2019).

Contributing to the evolution of paricide, virtual violence is now acknowledged as a risk factor associated with adolescent dating violence. It consists of “Monitoring, control, harassment, or verbal and emotional abuse of a partner through technology, cell phones, threatening text or voice messages, or online publications of insulting content” (Taquette and Monteiro 2019). This type of violence is associated with jealousy, an emotion mainly driven by love and anger, which is also identified as a risk factor for adolescents engaging in abusive behavior (Taquette and Monteiro 2019). There are various consequences of engaging in adolescent dating violence such as “Low self-esteem, depressive symptoms, psychiatric disorders, drug abuse, risky sexual behavior, and low academic performance” (Taquette and Monteiro 2019). Nevertheless, there is a lack of research among partner killing in adolescent populations (Taquette and Monteiro 2019).

LGBTQIA Community

According to Gaman and colleagues (2017), intimate partner violence is not anymore preventable within the LGBTQIA community than in the heterosexual community. When looking at paricide in this community, an individual has to notate the different roles each partner holds. Different roles and subcultures within this community include “bears, wolves, queens, princesses, butch, and lipstick (Biddle 1986).” Gaman and colleagues

Partner Killing, Table 1 Conservative, mid-level, and high-level estimates of the prevalence of intimate partner homicide among male and female homicides by region

	Total homicides of included studies	Conservative estimates (missing cases are regarded as non-partner homicides)	Mid-level estimate (missing cases are distributed as known cases)	High-level estimate (analysis is restricted to known cases)
Prevalence of intimate partner homicides among male and female homicides				
Worldwide (<i>n</i> = 32)	492,340	13.54% (9.24–18.23)	14.05% (12.97–20.43)	16.18% (14.07–20.73)
High-income countries (<i>n</i> = 18) ^a	476,537	14.92% (9.24–18.23)	18.38% (12.97–20.43)	19.42% (15.48–20.73)
Africa (<i>n</i> = 4)	4861	7.31% (5.65–18.31)	11.32% (8.61–18.58)	16.18% (12.62–18.57)
America (<i>n</i> = 3)	5112	0.72% (0.64–9.65)	1.33% (0.85–16.49)	4.68% (0.96–33.06)
Eastern Mediterranean (<i>n</i> = 0)	–	–	–	–
Low-income and middle-income Europe (<i>n</i> = 2)	419	10.98% (9.68–12.28)	11.16% (9.83–12.48)	11.16% (9.84–12.48)
Southeast Asia (<i>n</i> = 2)	601	18.75% (11.26–18.75)	22.04% (13.14–22.04)	22.74% (13.52–22.74)
Western Pacific (<i>n</i> = 3)	4810	4.82% (4.82–9.84)	5.55% (5.55–10.78)	5.68% (5.68–10.78)
Prevalence of intimate partner homicides among all female homicides				
Worldwide (<i>n</i> = 63)	133,691	38.55% (30.84–45.31)	42.71% (36.16–58.05)	47.36% (38.55–59.64)
High-income countries (<i>n</i> = 36)	115,515	41.19% (30.84–44.45)	44.95% (42.09–58.05)	48.56% (42.77–61.31)
Africa (<i>n</i> = 4)	6219	40.11% (38.55–41.67)	42.24% (31.93–45.72)	44.80% (42.25–47.36)
America (<i>n</i> = 15)	9658	40.54% (7.51–54.84)	42.54% (11.43–59.26)	42.60% (11.51–59.64)
Eastern Mediterranean (<i>n</i> = 2)	887	14.41% (5.26–23.56)	15.23% (5.56–24.90)	15.28% (5.58–24.98)
Low-income and middle-income Europe (<i>n</i> = 3)	200	20.00% (1.82–37.78)	20.40% (1.86–38.53)	20.41% (1.86–38.55)
Southeast Asia (<i>n</i> = 1)	80	58.75% (58.75–58.75)	62.10% (62.10–62.10)	62.30% (62.30–62.30)
Western Pacific (<i>n</i> = 2)	1132	19.12% (19.12–21.29)	20.22% (20.22–22.51)	20.28% (20.28–22.58)
Prevalence of intimate partner homicides among all male homicides				
Worldwide (<i>n</i> = 28)	373,077	6.28% (3.13–6.34)	6.47% (4.42–7.15)	6.48% (5.34–7.29)
High-income countries (<i>n</i> = 18)	364,410	6.28% (3.13–6.34)	6.59% (4.42, 7.15)	6.60% (5.34–7.29)
Africa (<i>n</i> = 3)	235	4.12% (1.55–6.38)	4.36% (1.56–6.47)	4.41% (1.80–6.48)
Americas (<i>n</i> = 2)	4580	0.43% (0.00–6.54)	0.81% (0.00–11.27)	4.00% (0.00–23.60)

Partner Killing, Table 1 (continued)

	Total homicides of included studies	Conservative estimates (missing cases are regarded as non-partner homicides)	Mid-level estimate (missing cases are distributed as known cases)	High-level estimate (analysis is restricted to known cases)
Eastern Mediterranean (<i>n</i> = 0)	—	—	—	—
Low-income and middle-income Europe (<i>n</i> = 2)	226	3.59% (3.18–4.00)	3.66% (3.24–4.08)	3.66% (3.24–4.08)
Southeast Asia (<i>n</i> = 1)	334	0.87% (0.87–0.87)	1.01% (1.01–1.01)	1.04% (1.03–1.03)
Western Pacific (<i>n</i> = 2)	3292	1.33% (1.33–2.78)	1.54% (1.54–3.22)	1.58% (1.58–3.30)

Data are number of homicides or median (IQR). *n* = number of countries with existing data

Stöckl et al. (2013)

^aThe high-income countries (classified by the World Bank20) included Andorra, Australia, Austria, Canada, Croatia, Cyprus, Czech Republic, Denmark, England and Wales, Estonia, Finland, France, Germany, Hungary, Iceland, Ireland, Israel, Italy, Japan, Lichtenstein, Luxembourg, Malta, Monaco, Netherlands, New Zealand, Norway, Poland, Portugal, Scotland, Slovakia, Slovenia, Spain, Sweden, Switzerland, and the USA

(2017) noted patterns of violence included 64% of lesbians using their hands as a weapon in abuse vs. 47.7% gay males and 51% of lesbians and 43.8% of gay males engaging in destruction of property during abuse. In addition, it was found that children of lesbian couples are more often to be exposed to physical violence five times more often than gay couples (McClennen 2005). Below you will see a distribution of victim–abuser dyads based on gender orientation out of 214 participants (Table 2):

Emotional Factors

When looking at the emotional component for these killings, research has shown men are more often to report anger due to instances of infidelity as the main feeling leading up to the killing where women tend to report anxiety and fear leading up to the killing of an intimate partner (Mize et al. 2009). Women have also been found to score high on self-defeating personality scales in response to abuse often accounting for why they do not leave the relationship sooner (Pico-Alfonso et al. 2008). In many cases, the feeling of fear is not only for themselves but also for their children during IPV

Partner Killing, Table 2 Valid surveyed victim–abuser dyads based on gender orientation

Abuse dyad		Frequency (percent) (<i>N</i> = 214)
Gender of victim	Gender of abuser	
Female	Male	146 (68.2%)
Male	Female	19 (8.9%)
Female	Female	18 (8.4%)
Male	Male	17 (7.9%)
Transgender	Female	3 (1.4%)
Female	Transgender	2 (0.9%)
Transgender	Transgender	2 (0.9%)
Gender unidentified	Female	2 (0.9%)
Male	Transgender	1 (0.5%)
Male	Gender unidentified	1 (0.5%)
Female	Gender unidentified	1 (0.5%)
Transgender	Male	1 (0.5%)
Transgender	Gender unidentified	1 (0.5%)

McClennen (2005)

and during this episode of fear is when parricide is at a higher risk of occurring (Johnson and Hotton 2003). Daly et al. (1982) found that estrangement often leads to a higher risk of uxoricide (wife-killing by a man), but not matricide (husband-killing by a woman). Kimmel (2002) suggested

that men who engage in violent acts often do so because of a desire to control, and their loss of control is what often motivates that violence.

Means Used to Commit Paricide

Supplementary Homicide Reports (SHR) and covered cases from 1976–2001, as seen in Table 3:

Motives to Commit Paricide

The social learning theory was also applied to paricide, where the individual learns that violence helps achieve desired behaviors through observing violent behaviors, especially in childhood (Olowu et al. 2011). Children often learn through modeling, and when men witness such behavior from their father in childhood, their likelihood of abusing their wives in adulthood increases (Olowu et al. 2011). Traditional values of males being dominant and women being passive and

submissive can also result in abusive relationships. In Nigeria, beating wives and children is considered a socially acceptable form of discipline (Aihie 2016). “Traumatic bond theory offers explanation on factors that can make women remain in abusive relationship while victim precipitation theory account for the role that victims plays in falling prey to spousal homicide especially men that are killed by their wives” (Ghosh 2015; Olowu et al. 2011). Olowu et al. (2011) found most events leading to the death of a spouse were accidental, rather than premeditated.

Married or Cohabiting

Looking at the relationship status for victims of paricide, we will explore being married, cohabiting, or non-cohabiting. According to research, men are more likely to commit paricide in a dating or nonmarital cohabiting relationship vs. a legal marriage, men were also found to be ten times more likely to be killed in a cohabiting

Partner Killing, Table 3 Frequency and percentage of killings by murder weapon employed as a function of sex of offender

Weapon	Male	Female	Total (%)
Firearm, type not stated	602 (1.9)	283 (1.5)	885 (1.8)
Handgun – pistol, revolver, etc.	15,018 (47.0)	9,216(50.3)	24,234 (48.2)
Rifle	2,001 (6.3)	966(3.3)	2,967 (5.9)
Shotgun	3,047(9.5)	1,167(6.4)	4,214(8.4)
Other gun	36(0.1)	19(0.1)	55(0.1)
Knife or cutting instrument – ax, icepick, etc.	4,934(15.4)	5,915(32.3)	10,849(21.6)
Blunt object – hammer, club, etc.	1,464(4.6)	232(1.3)	1,696(3.4)
Personal weapon – hands, feet, teeth, etc.	2,695(8.4)	97(0.5)	2,792(5.6)
Poison	40(0.1)	27(0.1)	67(0.1)
Pushed or thrown out of window	25(0.1)	2(0.0)	27(0.1)
Explosives	8(0.0)	6(0.0)	14(0.0)
Fire	196(0.6)	78(0.4)	274(0.5)
Narcotics and drugs	74(0.2)	27(0.1)	101(0.2)
Drowning	50(0.2)	1 (0.0)	51(0.1)
Strangulation – choking, hanging, etc.	842(2.6)	30(0.2)	872(1.7)
Asphyxiation	210(0.7)	14(0.1)	224(0.4)
Unknown	728(2.3)	229(1.3)	957(1.9)
Total	31,970(100)	18,309(100)	50,279(100)

Mize et al. (2009)

relationship (Mize et al. 2009). Furthermore, previous research found that women ages 35–44 were at the greatest risk for murder in a cohabiting relationship, as age was found to be a strong predictor in paricide (Shackelford 2001). It was also found that opposite to cohabitation, women in marriages are at greater risk for paricide if they are below the age of 25 (Shackelford 2001). For men, research has shown that husbands are less likely to be the victim of paricide as age increases, serving as a protective factor and the patterns described above have been seen in multiple countries such as Australia and the United States (Mouzos and Shackelford 2004).

Neurological Factors and Intimate Partner Killings

The last section that will be reviewed on this topic is a brief overview of the interplay of neurocriminology and neuropsychology. We will look at current methods that are being used to determine not only abnormalities in the neuroanatomy of the brain leading to intimate partner killings but also psychological factors that play a role in this criminal behavior. Davidson et al. (2000) were able to identify with the use of PET scans that murderers who committed the crime of killing due to reactivity had not only reduced prefrontal cortex functioning but also reduced glucose metabolism in the prefrontal regions. The amygdala was also found to have lowered activity in murders according to Laurell and Daderman (2005). When looking at the hippocampus, temporal lobe, and cingulate cortex, several anatomical factors are noted. The temporal lobe, which houses the hippocampus, appears to function abnormally in murders leading to acts of violence that include murder (van der Gronde et al. 2014). The anterior cingulate cortex is shown to have low reactivity in individuals who commit murder (Aharoni et al. 2013). In addition, according to a review done by van der Gronde et al. (2014), the prefrontal cortex has a large impact on executive functioning, which controls attention control, behavioral flexibility, working memory, self-awareness, and abstract decision making.

According to van der Gronde et al. (2014), looking at neurotransmitters and hormones serotonin plays a particular role in aggressive acts. Metabolic enzymes such as monoamine oxidase A (MAO-A) when reduced can lead to higher levels of serotonin, eventually leading to aggressive acts (Nelson and Trainor 2007). MAO-A, when in deficiency, increases reactive aggression (Baum 2013), and inversely testosterone was found to be in high levels when MAO-A was showing deficiencies (Vaske et al. 2011). As shown above, there are many neurological factors that play an important role in determining why a partner might commit the act of paricide, and further research is needed to continue building the connection between intimate partner killings and the reason why it occurs.

Conclusion

As evidenced throughout the chapter, paricide has evolved with the inclusion of motivational, emotional, and physiological factors. Earlier eras throughout history suggest paricide as an act of gaining power or status, leading to paricide being driven by emotional factors such as protection of offspring, jealousy, or aggression. Themes throughout the chapter raise question on whether it is fair to conclude patriarchal norms have contributed to paricide throughout history. From a physiological perspective, it is acknowledged that neurological abnormalities such as reduced functioning in the prefrontal cortex, amygdala, and levels of glucose metabolism in prefrontal regions have been noted in homicidal behaviors (Davidson et al. 2000). It is also important to note a history of witnessing domestic violence in childhood and adulthood are precursors to paricide (Olowu et al. 2011).

Partner Rape

Amelia Fazackerley and Joseph A. Camilleri
Westfield State University, Westfield, MA, USA

Synonyms

Forced in-pair copulation; Intimate partner sexual violence; Partner sexual coercion

Definition

Partner rape refers to nonconsensual sex between intimate partners

Partner rape (also called *forced in-pair copulation*) refers to nonconsensual sex between intimate partners and is considered a form of *partner sexual coercion* and *intimate partner sexual violence*, which are broader terms that include all forms of harmful sexual acts or statements toward an intimate partner (Camilleri et al. 2009; Camilleri and Miele 2016).

Partner rape is not uncommon, where estimates of its prevalence vary anywhere from 7% to 34%, (summarized in Camilleri and Quinsey 2012), with one estimate reaching 51% (Black et al. 2011). Such variation is due to differences in operational definitions and methodologies. Despite the variation, even conservative estimates show how widespread this form of sexual violence is, where some studies have found that it is as prevalent as acquaintance rape (Spivak 2011).

There have been almost no studies around male victims or female perpetrators, likely due to their low base rates. Research on partner rape has also been limited due to social, cultural, and legal norms that minimize or deny that partner rape exists (e.g., Lynch et al. 2016).

Causes of Partner Rape

One approach to understanding partner rape is to see if characteristics of sexual offenders in general apply to partner rapists. Camilleri and Quinsey (2009b) tested whether three main paths to sexual offending (young male syndrome, competitive disadvantage, and psychopathy) were associated with partner sexual coercion. Of these three paths, only psychopathy was found to be related to partner sexual coercion, where 33% of convicted partner rapists were psychopaths, and among a non-forensic sample, only psychopathy significantly correlated with self-reported partner sexual coercion propensity. Psychopaths' coercive approach to reproduction, among other cheater strategies, is hypothesized to have evolved through frequency-dependent selection (Mealey 1995).

Cuckoldry risk appears to be another important risk factor for partner rape. Cuckoldry risk is defined as the risk of female-partner infidelity that may result in men raising offspring who are not genetically related to them. Since cuckoldry risk posed a serious threat to reproductive success, men may have evolved ways to detect and minimize this risk. Partner sexual coercion, which includes partner rape, may be one such mechanism. In situations where cuckoldry risk is high (e.g., partner engaged in an extra-pair copulation during the most recent ovulatory cycle), we expect men to be more prone to engaging in partner sexual coercion. Many studies have found associations between cuckoldry risk and partner sexual coercion, using both forensic and non-forensic samples (Camilleri and Quinsey 2009a; Goetz and Shackelford 2006; Starratt et al. 2008).

Camilleri and Quinsey (2012) reviewed how partner rape could be understood in the context of sexual conflict theory. This theory suggests that

sexual conflict occurs when a benefit to one sex comes at a cost to the other sex, creating a selection pressure for counter-adaptations to evolve. This cyclical process may explain various sex differences in behavior and morphology. In the context of partner rape, there may be conflict in how often to have intercourse – women's lower interest may signal infidelity or possible loss of a partner, and men's sexual coercion may be an adaptive response to such a scenario. Another possibility is that women's extra-pair mating may increase reproductive success by copulating with a male with "better genes," and so partner rape may be a counteradaptation to reduce the risk of cuckoldry by engaging in sperm competition. Though theoretical and empirical work on this topic is starting to emerge, partner rape remains an understudied area of sexual violence (Camilleri and Miele 2016).

Synonyms

[Mating effort](#); [Parenting](#); [Paternal investment](#); [Paternity certainty](#)

Definition

It is the care devoted, directly or indirectly, by the male to his offspring, increasing their chances of survival and social success.

Introduction

Paternal care directed to the offspring is not unanimous in the animal kingdom. Among mammals, for example, a small group of species presents this type of behavior, among which are humans.

Paternal care may take on different forms (e.g., protection and feeding) and is usually conditioned to the reproductive strategies adopted (short or long strategy). This parental investment offers the offspring more chances of survival (e.g., lower mortality rates) and social success (e.g., more access to resources) (Geary 2016).

Particularities and Predictors of Paternal Care

Paternal care is a set of behaviors performed by a male directed to a member of his offspring and which has a positive effect on their development, growth, well-being, or survival (Fernandez-Duque et al. 2009; Geary 2016; Manfroi et al. 2011). The first attempts to explain paternal care emphasized the cost-benefit relations of the fathers' investment. Among them, two hypotheses should be noted: (1) paternal care evolved from the fact that biparental care increases their offspring's chances of survival and success; and (2) paternal care evolved as a male mating strategy, allowing a better relationship with their partners and strengthening their position in the broad social network (Fernandez-Duque et al. 2009; McNamara and Wolf 2015). However, current research has emphasized that the differences in parental investment are due to differences and conflicts between the sexes, in a process of choice and control conducted by the females (McNamara and Wolf 2015). That is, the evolutionary differences between the sexes would lead to this distinction in the use of parental care as a form of sexual selection and in the type and intensity of parental investment. In this process, the females exert the choosing power.

The differences in parental care can be the result of evolutionary trajectories of development under different social and ecological conditions. Parental care is difficult, demanding an investment of resources, time, and energy. While females invest more in their offspring and are more sought after for care, most adult males support their offspring selectively. The females' internal fertilization leads to uncertainty regarding the males' paternity among all birds and mammals, which impacts the paternal care expression. In

some species, this care is common (e.g., birds, fish), while in others it is infrequent (e.g., amphibians, insects) or relatively rare (e.g., mammals) (Fernandez-Duque et al. 2009).

In the case of mammals, fathers' participation is especially important due to the long pregnancies and lactation period the females go through. Despite being a rare behavior among mammals, primates stand out. However, even among them, only a small number of males assume a distinct type of relationship with their offspring. In these cases, paternal care is common, clear, and direct, remaining over the years. Paternal care in a few species of primates and in human societies includes sharing resources (e.g., food, tools), transportation, safety, imparting survival skills (e.g., hunting, escaping), and affection, among others (McNamara and Wolf 2015).

Human beings are one of the species that requires the most parental care after birth, and this investment is vital for reproductive success. However, this care is usually associated with the maternal figure, who carries and nurses the offspring. The care given by males is present in human societies in different intensities and forms and is considered to be a peculiarity of the species, seen as this behavior is not so common among mammals. Nevertheless, motor, emotional, and adaptive skills may be impacted positively by paternal presence (Manfroi et al. 2011).

The expression of paternal care varies greatly between different societies, ranging from complete absence to intimate and direct care. This happens for both foraging societies and developed and developing societies. Intercultural variability seems to be linked to social and ecological aspects of the environment (e.g., family extension, availability of resources, exposure to pathogens, mortality rate) (Fernandez-Duque et al. 2009; Geary 2016).

In adverse contexts, paternal care can make the difference in guaranteeing the survival and development of offspring. Still, it can also be used as a mating strategy, a kind of differential that qualifies the male. Paternal investment may function as a mechanism for the male to decrease the female's resistance (Manfroi et al. 2011; Smuts 1995; Trivers 1972).

Another important element that is usually associated with paternal care is paternity certainty. Especially in species where fertilization is internal, as in humans, only the female can be sure that the offspring are her descendants. Aiming not to invest in offspring who are not their own, paternal care is usually conditioned to a guarantee of paternity (Geary 2016). In this sense, a greater facial similarity perceived by human parents between them and the child significantly impacts the paternal investment exercised, since this would be an indication of paternity certainty (Yu et al. 2019). According to Geary (2016), paternity uncertainty is related to paternal abandonment. When there is an increased paternity certainty, paternal care may take place if this increases the offspring's chances of success or even if the cost is lower than the benefits. To ensure this certainty, several mechanisms have been developed for female control: sexual coercion, monogamy, seclusion, and other forms of female control (Smuts 1992, 1995).

There seems to be a link between the existence of affective connections, monogamy, and paternal care. This is because these processes seem to be regulated by a common biological substrate, with similar neuroanatomical and neuroendocrine activities (Fernandez-Duque et al. 2009). It is hypothesized, then, that the evolutionary computational mechanisms connected to paternal care are related to the same ones that promote general social behavior. Thus, it is likely that changes in the mechanisms that regulate socialization may elicit paternal care. However, there should be more studies to identify precisely the cognitive mechanisms and the forms of activation that facilitate paternal care expression.

Conclusion

In some species, the involvement of parents in the care given to the offspring is need for the survival of the descendants. Despite the high cost of parental care, females invest more resources than males. Paternal care is rare but, when present, may positively impact the development, well-being, and survival of the offspring, through material and emotional investment, as well as through support given to females.

Definition

Grandparents can invest a large amount of time and resources in their grandchildren. However, all grandparents do not invest equally in their grandchildren and usually paternal grandfathers are the ones who invest the least of all grandparent types.

Introduction

Males in several species invest in offspring as a function of paternity certainty (Platek and Shackelford 2006). This applies to humans as well (e.g., Alvergne et al. 2009), although among mammals, humans are an exception. Human males typically invest in their offspring unlike 95% of males of mammalian species, but human males also have potential uncertainty in their relationship to their children. While women can be sure that the child they gave birth to is biologically related to them, men can never be 100% certain that the child is actually theirs. In terms of grandparents, this means that only the maternal grandmother has no relationship uncertainty because she can be certain that her daughter

and her daughter's children are genetically related to her. Maternal grandfathers and paternal grandmothers have one kinship link with paternity uncertainty, but the paternal grandfather has two. Therefore, according to paternity uncertainty, paternal grandfathers are assumed to invest the least in their grandchildren (Euler and Weitzel 1996).

Empirical Evidence

Previous studies from contemporary societies have shown that paternal grandfathers usually invest the least in their grandchildren and that maternal grandmothers invest the most (see Coall and Hertwig 2010 for review). This is consistent with the hypothesis derived from paternity uncertainty and occurs in countries with no explicit preference for matri- or patrilineal family relations (Danielsbacka et al. 2011). However, cultural variation in matri- and patrilocality is shown to mix the pattern. The most obvious way to show the significance of cultural variation is to study patrilocal cultures in which a woman becomes part of her husband's kin after marrying (Kaptijn et al. 2013). This usually means that grandchildren will live much nearer to their paternal kin than their maternal kin and will probably only see their maternal grandparents occasionally. This naturally affects which of the grandparents gets to become the closest to the grandchild (Pashos 2000).

In addition to the two links of paternity uncertainty, the paternal grandfather is usually the oldest of the grandparents and is most likely to be either in the worst condition in terms of health or to have already passed away (Coall and Hertwig 2010; Strassmann and Garrard 2011). Old age and poor health may also diminish the investment made by paternal grandfathers, but when the age of the grandparent is taken into account, the paternal grandfather still invests the least (Danielsbacka et al. 2011). Another factor that is detrimental to the investment made by the paternal grandfather is marital disruption (i.e., divorce, widowhood, or remarriage) in the parental or the grandparental generation. Marital disruption does not deteriorate women's

relationships or decrease their contacts with their children or grandchildren as much as it does in men (Danielsbacka and Tanskanen 2016).

Conclusion

The paternal grandfather is predicted to invest the least due to several evolutionary important factors, including sex, lineage, and paternity uncertainty. In addition, age, health, and marital disruption are important factors that may be associated with paternal grandfathers' investment. Several studies from contemporary Western societies are consistent with the prediction that paternal grandfathers invest the least, although cultural variations (patrilocality) may change the investment patterns. However, humans may be unique among other species because caring paternal grandfathers actually exist at all.

Definition

The provisioning of caregiving-related resources (e.g., money, time) from fathers to offspring that will influence the probability of offspring survival and reproductive success.

Introduction

Humans are among the very few mammals in which males invest in the well-being of their offspring. Substantive paternal care is only found in 5 % of mammals (Geary 2000). Human neonates are born exceptionally helpless in comparison to other primates and remain dependent on caregivers throughout a lengthy juvenile. The rearing of large brained children who experience long periods of dependency requires a significant commitment of resources from *multiple* caregivers. An offspring's prospect for survival is inextricably linked to the ability and willingness of mothers and fathers to provide critical resources throughout development. Ancestral fathers were recurrently confronted with tradeoffs in how to best allocate finite resources to their offspring. The solutions to this adaptive problem of resource allocation are embodied in the ways that fathers continue to manage these tradeoffs today in modern environments. Natural selection has equipped human males with the capacity to invest resources in offspring.

Background

Investment of resources (e.g., money, time) to enhance one child's chances of surviving and reproducing come at a direct cost to a parents' ability to invest these same resources in other individuals including other offspring, mates, kin, and self (Trivers 1974). Among humans, paternal investment is facultative: Observed levels of care and the amount of resources a father contributes to a child's welfare fluctuate due to a multitude of environmental factors (discussed below) that can vary both within and between cultures (Geary 2000). Paternal resources may be material (e.g., money in industrialized nations or basic provisions in subsistence societies), temporal, social, skill based, attentional, and emotional. Over the course of human evolution, fathers had to make tradeoff decisions in how best to allocate these resources to offspring.

Male parental resources can be partitioned into direct care and indirect care (Kleiman and

Malcolm 1981). Direct care includes any investment such as feeding, playing, grooming, and interacting with the child in ways that benefit that child's survival in their local environment. Indirect care is a more removed form of investment (i.e., harvesting resources from the environment). Across cultures, the levels of direct and indirect care from fathers can vary significantly. Despite agreement that paternal care is a key feature of human child-rearing, debate exists regarding how much and when direct and indirect care can be expected from males.

Empirical work has found a handful of consistent predictors of paternal investment across cultures. Evidence suggests that fathers demonstrate increased levels of investment in children based on perceived paternity. In ecologies where paternity uncertainty (the probability that a male's purported child is indeed his biological offspring) is high, males demonstrate lowered levels of paternal care (see Geary 2000 for review). A higher level of paternal investment has been shown by those males that report being in satisfactory romantic relationships with their child's mother. In review of the literature, Gray and Anderson (2010) found that the most consistent predictor of paternal involvement across cultures was the level of relationship satisfaction a male reported to have with his child's mother.

Early life experience in a male's own development can influence the degree of paternal investment he expresses as an adult. When mortality risks are high or resources are scarce in early development, investing in more (rather than fewer) offspring can help ensure that at least some offspring will survive to reproductive age. In harsh, unpredictable, and low-resource environments, the psychological and physiological stressors on fathers are high, resulting in decreased levels of paternal investment. In safer, high-resource environments, father-child relationships are warmer and reflect higher levels of investment. There is some evidence that a father's own early childhood environment does indeed predict the level of paternal investment expressed in adulthood but others found no such relationship (see Geary 2000 for an extensive review).

Testosterone and Paternal Investment

The endocrine system, together with its interactions with the genome, provides a method of integrating diverse sources of input into messages transmitted throughout the body. This system coordinates behavioral and physiological responses to the environment. Neuroendocrine hormones, such as testosterone (T) in human males, are designed to be responsive to environmental stimuli – conveying important information throughout a male's body and across the lifespan to facilitate adaptive responses. Across diverse taxa, male paternal investment is largely influenced by T. T stands out as a candidate hormone to explore how paternal investment tradeoffs are mediated on the neurohormonal level.

Low T found in fathers of young offspring may indicate a tradeoff from investment in mating toward investment in parenting. While T facilitates intrasexual (male-male) competition for mates through avenues such as aggression, status seeking, and dominance, these behaviors may compete with parenting. Thus, there has been selection for lowered T levels coincident with increased paternal investment in a range of species that feature varying degrees of male involvement specific to rearing offspring. Cross-sectional research on humans from a variety has indeed demonstrated a relationship between a father's lower T and increased paternal care (e.g., Berg and Wynne-Edwards 2001).

Studies looking at the role of T in human paternal behavior have received increased attention. Most published work on human males in industrialized nations does indeed report lower levels of T in human males that are partnered in committed relationships and further reductions in circulating T in those males that have recently become fathers (e.g., Storey et al. 2000). These reduced levels of T are most pronounced in the immediate postnatal period to facilitate paternal care and then steadily return to baseline levels as the offspring develop – this latter shift is proposed to help facilitate a transition from parental effort back to mating behavior once offspring are comparably less dependent.

Muller et al. (2009), when comparing neighboring Tanzanian groups, found that Hadza fathers (known for high levels of direct paternal care) had lower levels of T compared to non-fathers, while no such differences in T were observed for the Datoga fathers (who provide little direct care, but do provision their young). Taken together, human males appear to follow a pattern of T-mediated tradeoffs resembling that of the avian species reviewed above – where circulating T increases to facilitate mating behavior and decreases to allow for direct paternal care. These studies on human males, while numerous, have relied on cross-sectional data which made it difficult to assess the direction of causality regarding T declines and fatherhood behavior.

Gettler et al. (2011) conducted a longitudinal study to clarify whether fatherhood suppresses T or if men with low T are more likely to become fathers. These researchers found that men with higher waking T at intake had greater mating success as evidenced by being in a stable partnership and/or becoming a father at follow-up. The largest declines in T were of those males that were newly partnered or were recent fathers and these declines were significantly greater than the age-related declines in T found in those men who remained single nonfathers. These results did not differ when the researchers controlled for self-reported stress and sleep quality. Within the group of males that experienced this decline in T, it was those fathers that reported investing more time in direct childcare who had the lowest levels of T – indicating a possible effect of direct care with offspring suppressing levels of circulating T. This study supports a model of T mediated tradeoffs in human males whereby high T predicts mating success and then T is greatly reduced after a man enters a stable mateship and becomes a father.

Paternal Investment and Offspring Developmental Outcomes

Men who currently live in resource-scarce environments are significantly more likely to be low-investing fathers, have reduced contact with their children, and/or become wholly absent

fathers (Geary 2000). This lack of substantive paternal involvement has a damaging trans-generational impact. Across cultures, children that are recipients of low paternal investment are more likely to commit acts of violence, engage in early sexual activity, at greater risk of becoming teenage parents, and becoming low-investing parents to their own offspring (Coley 2001).

In developing societies, there is a relationship between paternal investment and offspring mortality rates (see Geary 2000). Those fathers that do provide care, food, and time have infants that are, on average, in better physical health and this is the case across traditional societies as well as industrialized nations. Among the hunter-gatherer Ache of Paraguay, there is a highly significant difference in mortality rates for father-present versus father-absent children (Hurtado and Hill 1992). Father absence triples the probability of death due to illness and doubles the risk of the child being killed by other Ache.

Receiving substantive paternal investment also provides social competitive advantages to offspring by increasing a child's ability to compete for resources in adulthood. In industrialized nations, the degree of one's social competitiveness can be indexed by their educational achievement. Paternal investment (both direct and indirect care) is correlated with better academic skills in children and higher SES when these children reach adulthood (Kaplan et al. 2000). Furthermore, paternal investment in play (direct care) is associated with children's skill at regulating their emotions and with their social competence as adults (Geary 2000). Those children who have fathers who engage them in physical play are more likely to be popular than those children who do not regularly engage in this type of play. This popularity in childhood is expected to lead to increased social competitiveness in adolescence and, eventually, in adulthood.

Conclusion

Human fathers exhibit a substantial amount of plasticity with regard to the level of investment provided to offspring. As ecological conditions

do vary widely both within and across cultures, one should not be surprised to see this phenotypic variation in the level of care provided by fathers. The endocrine substrates that have evolved to support this facultative paternal investment also demonstrates similar (and closely aligned) variation from one ecological context to the next. The nature of the specific ecological cues that a father's endocrine and behavioral systems rely on for developmental calibration has yet to be entirely elucidated. The downstream consequences of low (or absent) paternal investment are far-reaching. Combining research efforts from multiple fields (e.g., evolutionary psychology, behavioral endocrinology, biological anthropology, and developmental psychology) has the potential to advance our understanding of the predictors of paternal investment in humans and, in turn, improve societally undesirable developmental outcomes in children.

Synonyms

Biparental care; Maternal investment; Parental effort; Parental investment; Sex differences in parenting

Definition

It is important to discriminate between two related but distinct constructs in evolutionary theory that

refer to parenting: (1) *Parental Effort* (PE) is the cost assessed in terms of *bioenergetic or material resources* of the production or maintenance of offspring, typically meaning that expended in behavioral parental care, but may also include biological gestation and lactation; (2) *Parental Investment* (PI), on the other hand, is the cost assessed in terms of the *production or maintenance of future offspring* of the parental effort presently expended upon *current offspring*. Presumably, the costs represented by parental investment are the direct consequences of the costs represented by parental effort, as the expenditure and depletion of available resources are the primary cause of limitations upon future offspring production or care, although not exclusively so. For example, Cabeza de Baca and colleagues (2016) provided a description of the additional costs of reproductive effort assessed in terms of physiological deterioration. Nevertheless, these additional physiological costs can be considered mostly indirect effects of the initial parental effort.

Technically speaking, the question of *maternal investment* versus *paternal investment* is therefore difficult to answer as the assessment of the cost in future offspring of resource expenditures upon the current offspring is rarely tractable and often inferential. In practice, the problem usually boils down to a comparison of the relative expenditures of *maternal effort* versus *paternal effort* as the relative *expenditures* of bioenergetic and material resources, which are more readily and directly measurable. A related question in many species that practice kin-selected alloparenting is that of the relative contributions of matrilineal alloparental effort versus patrilineal alloparental effort. Kin-selected alloparenting occurs when the genetic relatives of either the mother or the father assist in caring for the offspring, presumably to maximize their own inclusive fitness. The particular parent that is doing most of the parental care is therefore the most likely to recruit alloparental care from their own kin. In many human societies, for example, the mother typically contributes the bulk of the parental effort, and the maternal grandmother is often recruited to provide the bulk of the alloparental effort. Finally, further distinctions can be made within the matriline or

patriline providing alloparental effort, such as distinguishing between relative contributions of the collective female alloparental effort versus male alloparental effort. The case of the maternal grandmothers mentioned would then be classified as an instance of *female matrilineal alloparental effort*. Assistance from maternal aunts would also qualify within this category.

Introduction

Sex differences in parenting exist across many different animal taxa, most notably in mammals. These differences are posited to exist for many reasons that include anisogamy – differences in obligate parental investment based on gamete size (sperm vs. egg; Trivers 1972), ecological context, and sex ratio (Kokko and Jennions 2008), which modulates the intensity of intrasexual and intersexual competition. Under the assumption of anisogamy, the sex with the lower initial obligate investment in parenting – usually males – must compete to gain mating access to females. Females who typically have increased obligate investment must be more selective when choosing a mate, or risk mating with a low-investing partner that deflects on parental duties. In this scenario, females define the mating parameters of the ecology that emphasize choosing mates that are high-investing and/or physically attractive.

However, although anisogamy has been posited as the likely evolutionary *origin* of male–female differences in reproductive effort, about over a billion years ago in the “hot, thin soup” of the Precambrian seas where life arose, it is unlikely to be responsible for the subsequent *maintenance* of those traits in more complex multicellular organisms. What is more likely is that the ancestral anisogamy gave rise to a positive feedback loop in which females expended more and more parental effort to secure their initial reproductive investments and males did so to a lesser degree. In modern eutherian mammals, for example, the differential cost of an egg cell with respect to a sperm cell is trivial as compared with the physiological costs of gestation, lactation, and

parental care. These latter costs completely dwarf the initial cost of producing a single egg cell, however large it might be in comparison to a sperm cell. It should also be noted that male metazoans typically produce orders of magnitude more sperm cells than female metazoans do egg cells, and the relative costs of gamete production have rarely been considered in the aggregate. In summary, we need to go beyond the simple anisogamy model to correctly describe the relative selective pressures acting upon male and female metazoans with respect to their expenditures of parental effort.

According to *Sexual Strategies Theory* (Buss and Schmitt 1993), men as well as women have both short- and long-term sexual strategies, each with their own distinct tactics, which are strategically employed to maximize reproductive success in their respective environment. Because men and women differ physiologically, the adaptive problems they face vary. Acquiring resources to raise a child is an important problem women must face in selecting short- or long-term strategies and must weigh keeping a high-investing mate or limiting access to prospective mates. The primary adaptive problem men face is gaining sexual access to women. Thus, men are generally oriented toward investing more time and energy into mating than parenting.

Much within-species variation exists in parenting and mating behavior between the sexes. In species where both sexes are high-investing, such as in humans, the pattern of mating behavior resulting from anisogamy is altered, with competition for mate access increase in both sexes (Buss and Schmitt 1993). Contextual factors such as the sex ratio of males relative to females available to mate thus modulate intensity of intra- and intersexual competition. When the mating sex ratio is considered, the rarer sex controls the mating dynamics of the immediate environment. This means that in male-biased environments, male sexual behavior will be oriented toward parenting instead of mating; however, in environments where females are more abundant than males, sexual behavior of females and males will be oriented toward more mating and less parenting (Kokko and Jennions 2008).

The next section below briefly reviews between-species sex-differentiated mating and parenting behavior and focuses on the mating and parenting behavior in humans and nonhuman animals.

Evidences of PI Theory in Nonhuman Animals

Sex-role differentiation. According to parental investment theory, males are expected to allocate resources for the development of armaments and ornaments used during intra- and intersexual selection (Trivers 1972). Males are also predicted to destine a portion of their bioenergetic budget for searching and defending mates, whereas females are expected to be more selective (compared to males) when choosing a mate. This difference has been attributed to the costs accrued by females during reproduction including gamete production, incubation/gestation, nourishment, transport, and guarding behavior. Variations in parental effort then lead to differences in morphology, physiology, and behavior between males and females a phenomenon known as sex-role differentiation (SRD).

However, SRD is a continuum rather than a dichotomy, with ecological, social, and ontogenic factors moderating the degree of sexual differentiation on each species. Thus, even though a significant amount of evidence has been collected regarding sexual dimorphism, intrasexual competition and intersexual selection in fishes and amphibians, the absences of parental care in most the latter taxa (Reynolds et al. 2002), supports the fact that SRD is not fully reached. Furthermore, only 22 % of bony fishes (*Teleosts*) present some form of care (usually guarding the nest or the young). However, in those taxa where it has been found, male parental care is more widespread than female care. This phenomenon has been attributed to the fact that paternal care is correlated with external fertilization (89 % of bony fishes present external fertilization; Gross and Sargent 1985), whereas species displaying female guarding present internal fertilization.

In reptiles, SRD is also a heterogeneous phenomenon, where even though in most lizard (*Lacertilia*) species, males are larger than females, female-biased sexual dimorphism has been

described in turtles (*Testudinata*) and snakes (*Serpentes*; Cox et al. 2007). Furthermore different from other animal classes such as mammals or birds, parental care in reptiles is a rare phenomenon with only 4 % of lizards and snakes taking care of their young (Sinervo and Miles 2010). This reptilian pattern is not met by crocodilians, with most species displaying some form of parental care (~60 % of species present solely maternal care, whereas in 38 % of species males and females take care of their young; Grigg and Kirshner 2015) and with males usually being larger than females. Furthermore, in polygynous species, dominant males (i.e., “boss croc”) have been observed to copulate with multiple females, and defend their territory from invading rivals, while females protect the nest from predators and other conspecifics, assist the young when exiting the nest, carry their offspring to the water, and defend the crèche from predators and other adults (Grigg and Kirshner 2015).

In other clades, such as birds, some species do exhibit high levels of SRD, with males of numerous species being larger than females, as well as presenting armaments (e.g., spurs) and ornaments (e.g., plumages) lacked by females (Gill 2006). Moreover, behavioral differences have also been described, with males defending territories or performing complex displays during courtship rituals. However, since a main element of SRD is the level of parental effort expended by each sex, in birds 81 % of species exhibit biparental care (Cockburn 2006). Nevertheless, it is worth noting that most avian cooperative breeding species have altricial offspring (precocial: 4 %; altricial: 11 %), whereas the opposite is true for species relying exclusively of maternal care (precocial: 24 %; altricial: 7 %). Furthermore, in species where only one of the sexes invests in parental care, females more frequently take care of their young compared to males (females: 8 %; males: 1 %; Cockburn 2006). Consequently, in evolutionary terms, the degree of vulnerability of altricial hatchlings demands the attention of more than a single care taker, attenuating the degree of sex-role differentiation after fertilization but not before (e.g., intense males-male competition and female selection).

Evidence of SRD in extinct species remains a debated topic. However, descriptions of osteological, histological, and oological characteristics of nests, eggs, and remains may allow some degree of inference (Brusatte 2012). Thus, in clades such as *dinosauria*, evidence of sexual dimorphism has been attributed to differences in ornamentations as well as based on body size estimations. Furthermore adults dedicated a considerable amount of time to nest building (e.g., mounds or excavating holes), with nests of species such as *Maisaura peeblesorum* positioned adjacent to one another demonstrating a colony-type behavior (Brusatte 2012). The presence of multiple juveniles with poorly ossified bones also indicates that adults not only cared for several young simultaneously but that hatchlings were vulnerable and unable of an adult-type locomotion, requiring both active protection and provisioning. Additionally examinations of different types of parental care in relation to life history indicators (e.g., clutch volume and body mass) across 433 species of extant crocodilians and birds concluded that three extinct species of nonavian maniraptoran dinosaurs (*Troodon formosus*, *Oviraptor philoceratops*, and *Citipati osmolskae*) scaled better with respect to model including an avian paternal care model rather than with other forms of parental care (Varricchio et al. 2008).

Different from extant and extinct species of fishes, amphibians, reptiles, and birds with external fertilization, the internal fertilization and gestation of mammals not only increases the physiological costs accrued by females but it also releases males from directly investing in their offspring. Thus, across 1370 mammalian species, males have been found to be 10 % larger than females in 45 % of the taxa (Lindenfors et al. 2007). Furthermore, phylogenetic examinations have discovered significant differences in body size and canine size dimorphism across haplorrhine primates based on the level of intrasexual conflict (Plavcan 2004). Moreover, in most nonhuman primates males do not directly take care of their offspring, but rather females either on their own or with the assistance of kin not only protect the young from predators and

conspecifics but also carry and provide for their offspring (Gear 2000). Hence males allocate more resources to mating effort, whereas females to parenting effort.

Sex-role reversal. Parental investment theory is not restricted to predictions regarding circumstances where females choose mates and males compete for mating opportunities. Sex-role reversal (SRR), the occurrence of female-female competition and male choosiness over females, further has been described in fishes, amphibians, and birds.

In pipefishes and seahorses (*Syngnathidae*), for example, females have been found to deposit the eggs onto a brooding area located in either the tail or abdomen of the male (Foster and Vincent 2004). Moreover, male pregnancy (similar to female pregnancy in other species) has been found to be a costly endeavor. In seahorses (*Hippocampus* spp.) male gestation involves a considerable bioenergetic investment, including the osmoregulation of the brooding environment, transferring waste from the pouch into the blood stream, and synthesizing prolactin for the conversion of proteins to be consumed by the embryos (Foster and Vincent 2004). Although male brooding is considered a manifestation of SRR, the prevalence of female-female competition in *Syngnathidae* remains a highly controversial topic. Thus, whereas female intrasexual competition (and female ornamentation) has been observed in conjunction with male pregnancy in pipefishes, its occurrence is partial in seahorses (Wilson et al. 2003). Experiments with *Hippocampus fuscus* have found that female intrasexual competition is less intense compared to male-male aggression. The difference in female competition between pipefishes and seahorses has been attributed to the presence of social monogamy in former. This hypothesis has been supported by phylogenetic comparisons, where polygyny was found to be a better predictor of SRR in Syngnathids rather than social monogamy (Wilson et al. 2003). Even though further evidence is needed to determine the ubiquity of female-female competition in the genus *Hippocampus*, the co-occurrence of male pregnancy and female intrasexual aggression in other Syngnathids

supports the predictions made by parental investment theory.

SRR has also been described in amphibians. Paternal care (e.g., clutch attendance and carrying offspring) along with females' attraction to the vocalization of males in Poison-Dart Frogs (e.g., in *D. auratus*) support the occurrence of SRR (Eens and Pinxten 2000). This phenomenon was attributed to the time males were unreceptive while taking care of their young. The imbalance between the numbers of available males with respect to receptive females increased the competition among females for access to males (Wells 1978). However, similar to seahorses, observations with *D. auratus* have concluded that both males and females respond equally to competitive settings, despite the fact females are larger than males (Summers 1992). Thus SRR should be considered as partial in Dendrobatids. Additional studies with other Dendrobatid species could clarify the phylogenetic ubiquity of female intrasexual competition. In the meantime, more conclusive evidence of SRR in amphibians has been found in Midwife Toads (*Alytes obstetricans*; *A. muletensis*; Eens and Pinxten 2000), where males carry their young and females compete aggressively for copulation opportunities.

Similarly, instances of SRR have been observed in 35 species of five different avian families (*Scolopacidae*, *Centropodidae*, *Turnicidae*, *Charadriidae*, and *Jacanidae*; Eens and Pinxten 2000). In the Spotted Sandpipers (*Actitis macularia*), for example, not only males incubate, provide, and protect their young but females have been found to have more than one clutch per season with several mates. Females are also larger than males, a morphological trait associated to aggressive competitions for territories used to attract males (Emlen and Wrege 2004). Similarly, in Wattled Jacanas (*Jacana jacana*), males take care of their young, while females compete for copulations; moreover, sexual dimorphism is also reversed, with females presenting facial ornamentations and wing spurs, as well as being heavier than males (Emlen and Wrege 2004). Furthermore, in *Jacana jacana* SRR

extends beyond female intrasexual competition and male choosiness. After takeovers, females have been seen to destroy, evict, or kill the eggs or chicks of males who copulated with other females. Following the attack, targeted males not only copulate but also take care of the attacker's offspring.

Human Tests of PI Theory

The purpose of parenting is to raise viable, competitive, and reproductively successful offspring. Organisms must therefore decide how and where to allocate time and energy that best optimizes their level of reproductive effort allocated toward parenting and how much effort will be allocated toward different offspring (Ellis et al. 2009). While sex ratio matters, as discussed above, women face a unique burden that allocation of resources toward parenting is generally considered more vital to child survival than male parental effort (Hrdy 2009; Sear and Mace 2008). Because of this, human paternal care is highly variable and context-dependent, possibly facilitating transmission of status, quality, and social competency in offspring. Paternal effort in mammals is highly variable and rare. In Mammals, approximately 5 % of species have some form of paternal effort toward offspring (Geary 2000).

When do fathers invest in their children? According to Geary (2000), there are three things that must be considered when examining variation in paternal parental effort in mammals: (1) offspring survival, (2) mating opportunities, and (3) paternity certainty.

If male parental effort does not substantially increase offspring quality or survival, high-investing fathers will be selected against – the ecology will favor fathers who invest more in mating than parenting. Again, if paternal parental effort does not increase quality or survival of offspring, males will increase parental effort in mating than parenting. Only if there is a male-biased sex ratio will there be selection against low-investing fathers. In these situations, it may improve mating prospects to be mated to one female. Paternal effort and its impact is indeed highly variable. A classic example of

ecology-contingent fathering can be seen in the Aché and Hiwi hunter-gatherer tribes of South America (Hurtado and Hill 1992). Both tribes reside in areas where socioecological and environmental conditions differ. For instance, the Hiwi tribe live in an area of Venezuela where variable rainfall contributes to unreliable food and crop extraction; alternatively, Aché of Paraguay often experience constant rainfall that leads to abundant and reliable crops. According to Hurtado and Hill (1992), differences in resource extraction and male-male cooperation are essential among the Aché for group living. Male hunters within the Aché are in charge of hunting and collecting food for the entire tribe. Meat collected from group hunts is then communally shared, with no one in the tribe going hungry. Instead of focusing on male-male cooperation, Hiwi tribes emphasize spousal cooperation. For instance, during hunts, females assist males by helping collect carcasses or steering canoes, with food shared only among family members (Hurtado and Hill 1992).

Direct paternal involvement differs between males of both tribes. Hiwi fathers directly care for offspring and can be seen watching children while mothers are out gathering tubers. Paternal presence in Aché men involves little direct care. Instead, Aché males contribute protection for their offspring from unrelated males who may seek to harm or murder infants. Unstable pair-bonding contributes to higher male-male competition for mates that may include murdering the children of other males (Geary 2000; Hrdy 2009).

Both the Hiwi and Aché tribe demonstrate how socioecological factors may alter paternal involvement. Overall, Aché ecology is characterized by unstable pair-bonds, a male-biased sex ratio, and little parenting from fathers, while Hiwi ecology involves stable, long-term pair-bonding, more reproductive females than males, and direct care from fathers (Hurtado and Hill 1992). The effects of variable paternal presence on child mortality, as is expected, differ between both tribes; however, the effects are contrary to what is expected. For Hiwi children, paternal death and divorce had no impact on childhood mortality. Though it would be expected that

paternal death/divorce *should* matter in societies where fathers contribute direct care to their infants, it could be speculated that allomaternal bonds between the close-knit relatives living in the tribe could buffer against the effects of paternal death and divorce (Hurtado and Hill 1992). Additionally, divorce in Hiwi societies is extremely rare. Only 8 % of Hiwi children in the sample experienced pair-bond dissolution (Hurtado and Hill 1992).

While Aché males contribute mostly food provisioning and protection from unrelated males, paternal death and divorce (though common among the Aché) has an impact on child mortality. Specifically, father death and divorce has the most effect on mortality for children between the ages of 1 and 5 years old. Due to unstable pair-bonds and males seeking multiple mates, children from divorced families are more vulnerable to sickness, homicide, and capture in warfare (Hurtado and Hill 1992, p. 44).

The final factor to consider is paternity certainty. In environments where males have low paternity confidence in their offspring, it again makes most sense to invest time and effort mating. Investing time and energy raising children that are not biologically related to the male will result in net loss of resources and decrease inclusive fitness; however, in environments where paternity certainty is high, there would be an increase in paternal effort. Physiological differences between men and women, as was previously mentioned, affects reproductive strategies and affects the amount of investment the sexes contribute to parenting and mating (Trivers 1972). Additionally, paternal effort in children may also be affected by paternity certainty – fathers will seek to invest little in children if there is a chance that the offspring are *not* biologically related to the father (Geary 2000). The dilemma that males face in reproduction is that females do not display visible cues of estrus and, thus, are equipped with concealed ovulation. Thus, concealed ovulation presents an issue and a conflict of interest between the sexes with males seeking paternity certainty and females seeking male investment in their children (Geary 2000).

One possible mechanism that paternity certainty may work through is resemblance – whether the father believes the child resembles him. Phenotypic similarity (whether it is facial, physical, or behavioral) may be a proxy for genetic relatedness. Because investment in children is costly for males – with resources diverted from mating effort to support mothers in parenting – males must be highly discriminative and careful about investing in genetically unrelated children, which would be a waste of mating and parenting effort (Geary 2000). Paternal resemblance effects have also been noted in natural experiments involving fathers and their children. Fathers, whether presently in a relationship with the mother or not, reported higher levels of monetary investment toward their children if they reported increased paternal resemblance (Apicella and Marlowe 2004). Paternal resemblance has also been correlated between relationship quality of biological children and fathers, severity of injuries the mother received from the father, and amount of conflict between mother and father in a sample of males convicted of spousal abuse, with lower levels of perceived paternal resemblance increasing conflict and severity of injuries (Burch and Gallup 2000).

Competing Theories of Cooperative Breeding

There exists two broad set of theories regarding cooperative breeding in humans. The first focuses on the importance of mother-father cooperative breeding and the advantages the child incurs from this arrangement. The second set of theories posits that fathers are helpful, but grandmaternal alloparental care, care derived from someone other than the mother and father, is more important to child health and survival. According to embodied capital theory (Lancaster and Kaplan 2009), sexual specialization of labor evolved in primates, especially humans, due to a suite of adaptive traits called the human adaptive complex (Lancaster and Kaplan 2009) that advance brain development and long-term skill acquisition in young children. The human adaptive complex, which includes altricial young, long-term brain development, and delayed senescence, are

expensive traits that require large investments from mothers and fathers. Investment in somatic growth and reproduction, according to the theory, are investments in embodied “stocks,” where investment dividends are acquired through skill-acquisition and reproductive success (Lancaster and Kaplan 2009). In male-female cooperative breeding ecologies, sex-differentiated divisions of labor are vital for lower child mortality. When males and females focus on sex-specific tasks, the quality of childcare increases – while men are devoting long hours of hunting, which is a major source of calories in hunter-gatherer societies, females can allocate more energy in caring for dependent offspring without unnecessary exertion (Lancaster and Kaplan 2009). Hunting for women would be a source of unnecessary exertion if males did not participate in the task. Because women are caring for dependent offspring, hunting, which expends large amounts of calories, would not be ideal for women who are breastfeeding, since lactation is also a large caloric burden to the female, or seeking to get pregnant, which requires stored amounts of fat to maintain a pregnancy (Trivers 1972). Further, hunting is a skill-intensive task that requires long hours to master and long hours to perform and may be difficult with a dependent infant. If embodied capital is a long-term investment, it would be wise for a woman to complement a male in their skills than learn additional time-consuming skills. By allowing a spouse to hunt, women, aside from caring for young, can focus on harvesting foods that are high in carbohydrates (Lancaster and Kaplan 2009).

Other evolutionary theories postulate that male parental effort in children is expendable and can be replaced with allomaternal support from related females who can handle the burden of raising young (Hrdy 2009). In this view, parental effort from males will not necessarily matter in offspring survival or competency (Hrdy 2009; Sear and Mace 2008). The grandmothering hypothesis (Hawkes et al. 1998), a major hypothesis in this set of theories, posits that older, postmenopausal women are important to the survival and care of their grandchildren and increase their inclusive fitness by assisting in childcare versus

continuing their own reproductive capacity. Based on the principles of kin selection and paternity certainty, maternal grandmothers are hypothesized to be more investing toward their grandchildren than paternal grandmothers. A review of 45 studies found additional evidence suggesting the importance of maternal grandmothers in the survival of children and little evidence for the importance of fathers (Sear and Mace 2008). However, this analysis aggregated all natural fertility populations irrespective of subsistence economy, such as foraging versus farming, which might differ in the relative importance of male and female alloparents due to the different nature of their potential contributions.

Conclusion

The distribution of paternal to maternal investment across species is critically dependent upon a number of exogenous and endogenous factors, including the initial bioenergetic allocation of species-typical levels of parental effort, as governed by the dynamics of life history strategy, and the relative sex-typical bioenergetic allocations of parental effort, as governed by the dynamics of sexual strategies theory. These complex dynamics predict an entire continuous spectrum of partial reversals of the normative sex roles assigned by sexual strategies theory to males and females, respectively. These seeming anomalies do not count as either exceptions or objections to sexual strategies theory, as the specific circumstances under which these partial “sex-role reversals” occur is predicted by the basic dynamics that undergird parental investment theory.

Paternal Resemblance

Rebecca L. Burch

State University of New York at Oswego,
Oswego, NY, USA

Definition

Research indicates that men use child resemblance to make investment decisions as a strategy to prevent cuckoldry.

Introduction

Paternal resemblance based on shared features between the resident male and the child qualifies as a phenotypic indicator of shared genes. The literature overwhelmingly indicates that while both men and women can discern resemblance in others, there is a male specific effect of resemblance in child investment.

There are decades of studies stating the relationship between resemblance and male investment. Males who committed infanticide cited a lack of resemblance implying non-paternity as a reason (Daly and Wilson 1984). Resemblance has been implicated in the father/child relationship (Apicella and Marlowe 2004), with perceived child resemblance valued more highly by men (Volk and Quinsey 2002). Alvergne et al. (2010) found fathers reported the highest emotional proximity to children who displayed greater resemblance, but mothers did not. Alvergne and colleagues have also examined which facial features have the greatest effect on resemblance ratings by selectively showing parts of the face. Fathers were able to focus on specific resemblance cues even when the overall face was disrupted. Males also ignored facial features that fluctuated throughout development or failed to display resemblance cues.

Burch and Gallup (2000) examined this concept with 55 men in a domestic violence treatment program. The men answered several questions about the types of abuse they had committed toward partners, along with the relationships,

degree of relatedness, and perceived resemblance they shared with their children. Burch and Gallup (2000) also found that the presence of children that were explicitly unrelated to the male (e.g., children from a female's previous relationship or a stepchild) greatly increased the amount of violence in the home. In these instances, resemblance had no effect, as the men knew those children were not related to them. This indicates the underlying basis of paternal resemblance; the avoidance of cuckoldry. Cuckoldry, unwittingly investing in a child that is not your own, is a threat to fitness that is specific to males in species with internal fertilization (see ► [“Cuckoldry Risk”](#)). Because of this, men will avoid investing in children that are not their own, and decades of research (just as in the Burch and Gallup 2000 study) have shown that unrelated children are more at risk for abuse. Daly and Wilson conducted research in several cultures showing that non-biological parents are as much as 100 times more likely to kill their children than biological parents (Daly and Wilson 1985, 1996, 1998). Further, men have evolved strategies to determine if their children are their own. Phenotype matching, through paternal resemblance, is one strategy.

Burch and Gallup (2000) also found that these abusive males perpetrated more abuse, and showed increased severity of abuse directed toward their mates as the perceived paternal resemblance to the children decreased. That is, the more their children resembled them (in their own opinion), the better they treated, and the less they abused, their female partner. Their perceived resemblance to their children was also positively correlated to their relationship to and treatment of those children. The more the man thought a given child resembled him, the better he rated his relationship to that child, and the better he treated that child. As mentioned above, this effect was not seen with unrelated children, as the question of paternity with these children has already been answered.

Hypothetical Investment

Burch and Gallup (2000) show that the resident father's perception of resemblance plays a major

role in both partner and child treatment. However, there was no feasible or ethical way to experimentally alter child resemblance to examine differences in paternal investment. To do this, Platek et al. (2002) used imaginary children and hypothetical scenarios. Without the participants (undergraduate students) knowing, the faces of unknown children were digitally morphed with either images of the participants themselves or one of four other people of the same sex. Participants were then instructed to view a randomized array of children's faces, with one face resembling theirs. To measure the effect of shared facial features, the subjects were presented with hypothetical parental investment scenarios and asked to choose which child's picture they would invest in. Males chose their own morphed picture more often than females in almost every positive investment category (for example, which child they would spend time with, give money to, adopt, etc.) and less often in almost every negative investment category (which child they would physically punish, spend the least time with, etc.). The greatest difference between males and females occurred in response to the question, “Which one of these children would you be most likely to adopt?” with 90% of the males but only 35% of the females picking the child whose face had been morphed with their own. Likewise, none of the males picked children's faces that had been morphed with their own as the child they would be most likely to punish. In contrast, female participants reported having more difficulty choosing between hypothetical children, and several stated that they had tried to distribute positive and negative treatments as equitably as possible. In fact, two women halted their participation during the study, stating that the investment decisions were too difficult for them.

In a follow-up study, Platek et al. (2003) questioned whether these investment decisions were actually differences in the ability to detect resemblance; in other words, whether women would make the same decisions, but they could not accurately determine which child resembled them, or whether males were actually more likely to make decisions about child investment based on resemblance. The study showed no sex differences

in the ability to detect resemblance, but males were far more likely to make hypothetical investment decisions that favored children who looked like them.

Resemblance, Investment, and the Brain

To take this even further, Platek et al. (2004) used the same paradigm paired with magnetic resonance imaging to examine sex differences in neurological activation when viewing self-morphed baby pictures. Unlike females, males showed significant neural activation in the left frontal cortex (which is hypothesized to be involved in the inhibition of negative responses) when viewing children's faces that resembled them. Platek et al. (2005) also found that males showed greater cortical activity than females in response to children's faces that resembled them. Using a similar design, Wu et al. (2013) also showed that men showed higher detection of resembling child faces and self-referential processing in kin detection than did females. In total, these studies show a male advantage in resemblance and investment assessment that utilizes multiple areas of the brain and occurs at different stages of processing. Male brains may be designed to process children's faces and make investment decisions based on resemblance.

Adult Versus Child Faces

Differences in research methodologies illustrate how men and women may process faces in similar ways but differ significantly in how this affects decision making. DeBruine found a resemblance effect in cooperation and prosocial behaviors in adults but no gender difference (DeBruine 2002, 2005). However, she used adult faces, not child faces. Platek et al. (2004) found sex differences in brain activation to resembling child faces (Platek et al. 2004) but not adult faces (Platek and Kemp 2009). What is found throughout the literature is that gender differences are only found when children's faces are used. While Burch et al. (2006) imply this may be the case, Lewis (2011) makes it

clear: "The different contexts in which previous studies investigated resemblance effects may account for this apparent inconsistency. Platek et al. (2002, 2003) examined prosocial behavior toward children. Because of paternity uncertainty, facial resemblance would be expected to have a greater effect on men's than women's parental investment. DeBruine (2002, 2004, 2005), on the other hand, assessed prosocial behavior toward peer-aged individuals." (p.970). Therefore, both men and women have evolved to detect and utilize resemblance to make decisions like trust and cooperation, but men use this cue for child investment.

This resemblance, or phenotype matching, may extend to sensory modalities other than vision. Alvergne et al. (2009) found that paternal investment was positively related to both face (visual) and odor (olfactory) similarities between fathers and children. Research has yet to determine what neurological areas (or if the same neurological areas) may be implicated in olfactory phenotype matching processing. Gallup Jr et al. (2016) showed greater paternal investment in children based on shared psychological features (interests, attitudes, etc.). While both physical and psychological features made a difference, shared psychological features between fathers and adolescents and older children accounted for even more variance in measures of paternal investment than physical resemblance.

Maternal Strategies

Given these findings, it is understandable why mothers and their relatives often try to convince fathers of their child's resemblance. Daly and Wilson (1982) recorded spontaneous remarks in maternity wards about the appearance of the newborn child. Mothers, friends, and relatives were more likely to comment on how children resemble their fathers. When fathers voiced doubt, the mothers quickly reassured them of the child's resemblance. One father made it clear that if the child did not resemble him, he would leave the mother at that instant. Regalski and Gaulin (1993) also found that women consistently ascribed

resemblance to their current male partner, and Alvergne et al. (2007) found that mothers ascribed resemblance to the father, even when assessment by external judges revealed the opposite. Females consistently ascribe resemblance of their children to the resident father, because it may increase investment, decrease abuse, and ensure their child's survival.

Conclusions

Decades of research have shown that men use resemblance as a measurement for child investment decisions that male brains process resemblance cues differently specifically when making these decisions (and not when processing adult resemblance), and that women have developed counter strategies, attempting to convince fathers of resemblance where none may exist.

Definition

Male parent of the child typically seen as a secondary role to the maternal position.

Introduction

It is clear times have changed in most societies when one looks at the role of the father from the primitive eras to the twenty-first century. Fathers typically are seen as a secondary caregiver in most societies around the world, while the woman is mainly responsible for the child, especially in the beginning critical stages of life. So, this begs the questions of what roles males typically have in the development of their offspring, and what happens when there is an absence of this?

Evolution of the Paternal Role

Various pieces have investigated the differences of maternal from paternal roles and what investment fathers have in their children. Typically, it was believed that men in order to maximize their reproductive success would attempt to reproduce with as many females as possible. Males were typically known to invest more in mating rather than supporting their child because doing such would waste resources that could otherwise be spent on spreading their genes (Geary 2000). This means only when they could not continue to mate with other females that males would support their children, but only if they were confident about their paternity to the child. When fathers did remain present in their children's lives, their main role was to provide protection to the family unit. Studies have looked at the likelihood of children and mammal offspring in general survival rates with and without a father present, and when there is the absence of a paternal role, the offspring usually suffer with those living – not being as healthy or large (Geary 2000). Animals differ greatly when it comes to the role of the father with predominantly carnivorous mammals, such as wolves and foxes; fathers aid the mother in hunting, protection, and are even seen playing with their young often. Yet, looking to our most closely related relatives such as chimpanzees, you will see that they are commonly uninvolved.

Recent investigation of the paternal role from Gray and Anderson's *Fatherhood: Evolution and Human Paternal Behavior* has shown a light on the assumption of past hunter-gathering tribes negating the view that men hunted for their children (Gray and Anderson 2010). Recent evidence they have done has suggested that men hunted for the entire tribe to share with other members, and their children were just included in the feasting. However, this sharing of food was mainly done in hopes of creating a reputation among other males in the tribe and attracting other women to mate with – feeding their children was just assumed to happen since they were part of the tribe. Not to say that they were uninvolved fathers, much of their time spent

hunting was to bring extra calories for the mother since they were less able to provide for themselves.

Family Dynamic

Typically, it is most usual for a male to have multiple wives, therefore a child to have more than one mother. Think of the old saying “it takes a village to raise a child” with many members of the tribe aiding in the infants’ survival. But in some Amazonian communities, it was and still is typically for a child to have multiple fathers (Hrdy 2009). “Partible paternity” was a concept Sarah Blaffer Hrdy coined in her book *Mothers and Others: The Evolutionary Origins of Mutual Understanding* which addresses a compelling topic for the idea that humans evolved the context of communal child care, where more than one father claims responsibility for the same child. Hrdy believes this arose as a result of extreme violence among rival tribes where many children lost their biological fathers so another male in the tribe stepped up. In a case such as this, having a strong male protector could mean life or death.

Conclusion

It’s clear that although shifts are happening between men and women caretaker roles, predominately we still see this being true in the twenty-first century where the mother is predominately responsible for the critical stages of the infant development, where the father will go out to work. Fathers can still be a valuable asset to a child’s well-being, and when it comes to healthy upbringing, the more positive bonds, the better.

Definition

It is the certainty perceived by the male parent that he is the biological father of the offspring.

Introduction

In most species of birds, mammals, and in some fish, extensive biparental care is observed (Safari and Goymann 2018). The amount of parental investment varies considerably, with females typically investing more than males (Safari and Goymann 2018). Caring for offspring demands an investment of time and resources, which competes with future reproductive success (Trivers 1972). Thus, certainty of paternity is, for many species, key for paternal investment. Mechanisms which may have developed to address this issue include the formation of monogamous couples, the sexual control of females, and different degrees of parental investment.

Paternity Certainty and Paternal Care

In species with internal fertilization like mammals, mothers are always completely sure about her relationship with her offspring. However, fathers never have total certainty. Thus, paternal care is usually subordinated to degrees of paternity certainty (Geary 2016). The essential uncertainty in paternal lineage affects even the amount of investment given by grandparents. Some research suggests that human maternal grandmothers show more investment in grandchildren than paternal grandfathers (or even paternal grandmothers). While the first group does not have any uncertainty about kinship, the second group has two uncertain events of kinship. Such findings enforce the relationship between relative degree of certainty of paternal kinship and differentiation in care (Bishop et al. 2009).

In a review of data concerning this issue, Geary (2016) points out some tendencies: (a) when there is low paternity certainty, selection favors paternal abandonment; (b) when there is high paternity certainty, selection favors paternal investment if its enhance chances of survival of the offspring or if the costs are lower than the benefits; and (c) when both certainty of paternity and associated costs are high, selection favors a mixed strategy influenced by ecological conditions. Despite all these factors, paternal care is a rare feature in nature. It is most commonly related to monogamy, although it is

observed in only 59% of monogamic species (Lukas and Clutton-Brock 2013).

Some male behaviors concerning the control of the sexual behavior of the female can be viewed as strategies to increase paternity certainty. Such control includes use of coercive force and aggressions as a way to internalize submission towards the male; demands of reclusion and proofs of non-promiscuity from the female; and subordination of the degree of paternal investment to the degree certainty offered by the female (Smuts 1992, 1995). Some group strategies include the formation of monogamous families through marriage and moral control over women, as laws of behavior or patriarchal ideologies (Smuts 1992, 1995).

Strategies to identify and deal with paternity uncertainty vary widely among species. Some species of fish rely on the visual detection of cuckolders to modulate their paternal investment (Gray et al. 2007). Depending on a combination of factors that also includes low prey availability, low energy reserves, and mate availability, the male may cannibalize the current brood in order to restore the energy lost in that brood and be ready for a new fertilization (Gray et al. 2007). In humans, researchers have shown that the perceived father-child facial resemblance influences the disposition to paternal care but has no effect on maternal investment, suggesting that perceived facial resemblance should be one of mechanisms underlying the verification of certainty paternity (Yu et al. 2019).

In species of birds, the temporary escape of the nest by the female is taken as an indicator of paternity uncertainty concerning the eggs delivered after her return. However, in some species of socially monogamic passerine birds, extra-pair paternity is a common feature, and investment in non-kin brood is also common. Even with experimental manipulations of the degree of uncertainty of paternity, these males expend the same amount of investment in paternal care towards the offspring (Kempnaers et al. 1998).

Conclusion

Certainty of paternity is a framework that synthesizes a set of variables to describe the conflict

between paternal investment and future reproductive success and thus interferes with the amount of investment that males can devote to offspring. This framework is related to evolutionary mechanisms such as the sexual control of females, monogamy and social control that, as a whole, can increase the male fitness. Insights concerning the evolutionary importance of paternity certainty can shed light on some cultural phenomena such as child neglect and male reluctance to support biological children.

Definition

The uncertainty faced by males related to whether or not an offspring is his own. An adaptive hurdle that puts males at risk of raising offspring that do not share his genes.

Introduction

Males and females differ when it comes to parental investment (Trivers 1972). Given that females pay high costs to create one offspring, they tend to be more selective as to which mates they choose and typically pursue long-term mating strategies. Males, on the other hand, do not have to pay the costs of gestation and childbirth, and the cost of producing one offspring is only the time spent impregnating a female. As a result, males tend to be less selective as to whom they mate with, often pursuing short-term mating strategies. When a male does decide to stay and invest on a child, however, he is voluntarily sacrificing time and

resources that could be otherwise spent searching for additional mating opportunities. By increasing parental investment, both males and females increase the likelihood that their offspring will survive into adulthood and further reproduce. If an offspring is illegitimate, however, a male may spend crucial time and resources on an offspring that does not share his genetic lineage. As a result, paternity certainty is of uttermost importance. Whereas an individual female can be entirely sure that a child is hers, an individual male has no such insurance. Thus, males have evolved a set of mechanisms to avoid such cuckoldry and prevent rearing offspring that are not truly kin. Alternatively, women and other relatives have also evolved mechanisms meant to ensure that the male will believe the child is his and thus help in the rearing. These mechanisms are described in the following section.

Biological and Behavioral Adaptations Related to Paternal Confusion

While there is no questioning whether or not a child belongs to its mother, fathers cannot always be certain that an offspring is their own. As a result of paternal uncertainty and low parental investment in males, both males and females have evolved different adaptations to these adaptive hurdles.

For instance, Gallup et al. (2003) suggested that the penis has evolved morphologically in such a way that it can scoop the semen of competing males out. Over time, the male phallus has evolved from being flat, as seen in chimpanzees, to having a prominent coronal ridge for this purpose. In relation to this idea, the researchers also observed that deeper and rougher thrusting has been related to potential infidelities in heterosexual couples, with males that suspect infidelities in their relationship thrusting deeper and more frequently. This further suggests that the shape of the human penis has evolved to prevent cuckoldry, as harsher thrusting would possibly displace more semen.

While the shape of the penis is a biological adaptation to prevent cuckoldry, there are also

additional behavioral adaptations that can be seen in males to protect against paternal uncertainty, such as mate guarding. Buss (2002) defines mate guarding as strategies used to preserve access to a mate while preventing access to that mate from rivals and preventing a mate from defecting in the relationship. Examples of this include keeping a mate away from potential competitors, engaging in behaviors such as public displays of affection, feelings of jealousy, and male proprietariness behavior, which entails a man laying a claim over a particular woman and thus advertising and exercising the intention of defending this “property” (Wilson and Daly 1992).

Paternal resemblance is often another factor involved with male behavior and cuckoldry. Burch and Gallup (2000) observed that males reported lower quality relationships with their children when their perceived paternal resemblance was low (i.e., when, according to the male, his child does not resemble him all that much). Among male domestic violence perpetrators, the severity of abuse was reported to be more severe among men who reported lower levels of paternal resemblance in their children. Additionally, males were more likely to share resources with children who looked the most like them. In response to paternal uncertainty, paternal assurance tactics have evolved as well, mostly so that females who have cuckolded a man can convince him that the child is his, thus guaranteeing the man provides resources and aids in child-rearing. Research by Daly and Wilson (1982) states that suggesting paternal resemblance when a child is born is a paternal assurance tactic. After the birth of a child, the mother and the mother’s relatives are typically more likely to report that the baby looks more like the father, as opposed to looking like the mother.

Conclusion

As a result of females becoming pregnant and giving birth, there is no question as to whether or not an offspring is hers. Males, on the other hand, have no such insurance. In order to avoid

cuckoldry, males have evolved biological and behavioral adaptations to avoid rearing kin that is not their own. In response to these adaptations, women have evolved paternal assurance tactics. Typically, other relatives on the woman's side also engage in these tactics to ensure that a male will help raise the woman's child. Additionally, research has shown that paternal uncertainty has been related to relationship quality with one's kin, resource sharing, and abuse.

Definition

The following entry discusses the concept of paternity uncertainty and the subsequent effects that it exerts on behavior, particularly in terms of offspring investment and conflict.

Introduction

Generally, parental certainty (how confident that an offspring produce by a partner is genetically related) differs between females and males. In humans, a female is certain that a child she has carried is genetically related to her (maternal certainty). In contrast, males cannot know for sure that his sperm, and not the sperm of another male, fertilized his partner's egg (paternal uncertainty). Hence, a human female is *completely certain* that her offspring are genetically related to her whereas a human male is not. Paternity

uncertainty sets the stage for conflicts between females and males as well as between males and putative offspring (i.e., father-offspring conflict).

Paternity Uncertainty and Father-Offspring Conflict

Because a mother and her offspring are unquestionably genetically related, a mother stands to gain greater genetic fitness (i.e., passing on her genes to future generations) through parental efforts (e.g., caring for, feeding, spending time and money, etc.) than through mating efforts (e.g., seeking and finding extra mating opportunities). She can be confident that her offspring and any offspring produced through the matrilineal line carry her genes. Any parental investment that she provides promotes their and, through them, her reproductive success. In contrast, a male stands to gain greater genetic fitness through mating rather than through parenting efforts *particularly if he is uncertain he is the biological father*: Investing in genetically unrelated offspring adds little or nothing to a male's direct genetic fitness. For a male, greater mating efforts increase the likelihood that at least some offspring are genetically related to him. Hence, paternity uncertainty places a male in a dilemma: Continue parental efforts (to invest in offspring that may be genetically unrelated) or reduce parental efforts and increase mating efforts (to increase the probability of producing genetically related offspring). Trivers (1972) was the first to propose that males, each of whom face paternal uncertainty, reduce parental investment for putative offspring relative to females who enjoy maternal certainty. Interestingly, a body of research demonstrates that maternal grandparents (certain of genetic-relatedness to distal offspring) invest more highly both financially and emotionally in grandchildren than do paternal grandparents (uncertain about genetic-relatedness to distal offspring; Michalski and Shackelford 2005; Bishop et al. 2009). The same finding has been documented in aunts and uncles, with both showing a matrilineal bias in terms of investments made (McBurney et al. 2002).

The sex-based asymmetry in parental certainty contributes to a variety of conflicts between males and females and to conflicts between males and putative offspring (Trivers 1974). Specifically, a male may come in conflict with offspring as he and the child attempt to further their own genetic success. As said, a male who is uncertain that the offspring shares his genes stands more to gain genetically by reducing investment in the child and increasing investment in mating and reproduction. In contrast, a child who receives continued investment from the male (regardless of genetic-relatedness) benefits in terms of its own reproductive success. This sets the stage for *father-offspring conflict*, a phrase that refers to any investment the male makes in the child (e.g., care, protection, provisioning, etc.) that detracts from the male's ability to produce and invest in additional offspring while simultaneously facilitating the reproduction and survival of genetically related offspring. Put differently, paternal uncertainty contributes to a propensity for a male to *reduce parental investment* (reduce parenting efforts) whereas the reproductive success of offspring contributes to a propensity for an offspring to *maximize parental investment* (induce increased parenting efforts) from the male.

There are strong empirical relations between paternal uncertainty and father-offspring conflict. For example, males are particularly sensitive to paternal resemblances. Physical similarities between the male and the offspring predict paternal investment: Fathers invest more in offspring that share a physical resemblance to him relative to less physically similar offspring. In one study, depictions of participant faces were morphed into photographs of children. Answering a series of hypothetical questions, males reported that they were more likely to adopt, spend time with, and spend money on the face best matching their own facial features (Platek et al. 2002). Similarly, men who perceive their offspring as physically similar to themselves and who report greater perceived partner fidelity provide the greatest parental investment (Apicella and Marlowe 2004). The same patterns of paternal investment are found in a polygynous population in rural Africa. In this sample, both facial and odor similarities between the father and offspring predict the extent

of paternal investment. Moreover, the extent of paternal investment predicts childhood health; children receiving more paternal investment showed superior growth and nutritional status (Alvergne et al. 2009). Finally, paternal resemblance appears to be an important predictor of the likelihood of domestic violence: The greater the perceived physical discrepancy between the father and offspring, the greater the probability of violence in the family (Burch and Gallup 2000). Taken as a whole, a growing body of evidence points toward positive relations between paternal uncertainty and parental efforts, suggesting that males use, among others, cues of offspring resemblance as indicators of genetic-relatedness and parental certainty.

Conclusion

Females enjoy absolute certainty that offspring they deliver are genetically related; males always run a risk of those offspring being genetically unrelated. This asymmetry anchors diverging patterns of parental investment on the part of females and males. A female's fitness is more likely to be enhanced through parental investment in offspring that she delivers. In contrast, a male must decide whether to continue parenting efforts (investing in the offspring with the risk that he is not genetically related to the offspring) or switch to mating efforts (investing in efforts to mate and reproduce which increase his chances of producing his own genetically related offspring). Signals that offspring are genetically unrelated to the male (e.g., perceived fidelity of the female, differences in child/male physical characteristics) increase the likelihood that the male will reduce parental efforts and increase mating efforts. Given that it is in the offspring's best genetic interest to extract as much investment from the parenting male as possible, a foundation is laid for father-offspring conflict.

Definition

Paternity uncertainty is when a putative father is uncertain of whether he is unknowingly investing in a genetically unrelated offspring.

Introduction

Parenting is an important evolutionary behavior that is associated with high costs such as reduced mating opportunities and somatic health and maintenance (Trivers 1972). However, these high evolutionary costs are offset by the investments in offspring that help to increase chances of offspring survival and reproduction. Thus, the benefits of parenting from an evolutionary perspective are strongly tied to parents investing in biologically related children. This is generally not a concern for women as the physiology of human reproduction means that mothers always know whether an offspring is genetically related to her or not. However, fathers do face the problem of paternity uncertainty, in which they could be unknowingly investing in a child that is not biologically related to them (Geary 2006).

Paternal Investment and Paternity Uncertainty

In order to reduce paternity uncertainty, men are theorized to initially engage in mate-guarding behaviors, in which they may conceal their mates from other rivals and/or physically prevent their mates from being taken over by rivals (Haselton and Gangestad 2006). However, as the prevalence rates of paternity uncertainty in humans are shown to average at 1.9 % (Anderson 2006), fathers may have predispositions to detect false paternity.

As such, father-child facial resemblance and offspring sex may function as proxies to determine genetic relatedness and levels of investment, respectively. Determining genetic relationship through facial resemblance is theorized to be a mechanism used by ancestral and present day fathers (Geary 2006). Studies have found that

fathers invest more into offspring which have higher levels of facial resemblance to themselves (see ► “**Resemblance**” chapter). Fathers may also be investing more in sons, compared to daughters, so that their sons can attract desirable and loyal mates (Bishop et al. 2009) and consequently reduce chances of cuckoldry. This may help to maximize genetic fitness for both fathers and their sons. In support of this theory, studies have found that boys, compared to girls, receive higher levels of paternal investment across cultures (Marlowe 2005), suggesting that paternal uncertainty may not only be a concern for fathers but also for grandfathers.

Grandparental Investment and Paternal Uncertainty

Investment in kin is strongly associated with the certainty of genetic relationship, even across generations (Trivers 1972). In terms of genetic certainty, maternal grandmothers (MoMo) have the highest genetic certainty of their grandchildren compared to paternal grandfathers (FaFa), because MoMo’s can be certain that their daughters are genetically related to them and that their grandchildren are genetically related to their daughters. However, FaFa’s do not have the same levels of certainty as they and/or their sons could be raising offspring that are not genetically related to them (Bishop et al. 2009). As a result, studies have found that grandchildren receive higher levels of investment from grandmothers, such as more frequent contact and emotional closeness with their grandmothers, compared to grandfathers.

Adoption and Paternal Investment

How do these findings compare to adoptive father-child relationships? From a kin selection perspective, adoptive parents should provide the least investment in adopted children due to lack of biological relatedness (Hamilton et al. 2007). However, studies have found that adoptive parents display similar or even higher levels of

parental investment. Researchers propose several explanations for these findings. First, adoptive parents do not have to worry about the presence of a rival (the biological father) who may steal the mate (Hamilton et al. 2007). Second, adoptive parents may be highly and intrinsically motivated by a strong desire to care for children (Hamilton et al. 2007; Volk 2011). Third, adoptive parents may be engaging in “kinning” (Howell 2003), where the investment in an unrelated child is an attempt to socially construct kin relatedness (a socially, but not genetically, viable strategy). Fourth, investing in an adopted child may allow for future support from grown-up adopted children if one lacks such support from one’s biological children (Volk 2011). Fifth, since humans today no longer frequently live in close-knit communities as they previously did, the parental care seen in adoptive parents may be derivative of a general predisposition to care for other’s children as a form of reciprocal altruism (Hamilton et al. 2007). Sixth, adoptive parents may be triggered by proxies of genetic relatedness as adoption agencies try to match adopted child based on facial resemblance with adoptive parents (Herring 2003). This is possibly because the adopted child is quite often a substitute for the lack of a biological child and therefore social and emotional mechanisms are required to help scaffold the lack of actual genetic relatedness (see ► “Resemblance” chapter).

There is currently less research regarding whether adoptive fathers invest more in adopted sons compared to adopted daughters. However, given the findings that (a) biological fathers may be investing more in sons to increase inclusive fitness, (b) adoptive parents may be influenced by cues of facial resemblance, and (c) fathers’ perceptions of genetic relatedness may be more strongly influenced by social and emotional cues (Volk 2011), it can be suggested that the predisposition of increasing level of investment for sons may also be triggered in adoptive fathers when facial resemblance to the adopted son is high. Put differently, facial resemblance may moderate the association between level of investment and sex of adopted child for adoptive fathers.

Conclusion

Evolutionary theories have generally theorized that paternal investment may be largely driven by perceptions of paternity (un)certainty for fathers and grandfathers. However, it is interesting that even though paternity uncertainty is highest for adoptive fathers compared to “biological” fathers, adoptive fathers are shown to provide moderate to high levels of investment in their adopted children. This is essential to understanding overall parenting, as nongenetic motivations may also be driving parenting behaviors (Volk 2011). However, few studies have investigated parenting in adopted families (Hamilton et al. 2007; Volk 2011) and even less have analyzed paternal caregiving in adopted families. As human evolution and parenting are suggested to be influenced by adoption practices (Volk 2011), additional empirical studies of adoptive families from evolutionary perspectives are important to advancing the parenting field.

Paternity Uncertainty Hypothesis

Ryan Colclasure
Western Illinois University-Quad Cities, Moline,
IL, USA

Synonyms

“Cads and dads”; Cuckoldry; Parental investment; Paternal discrepancy; Paternity certainty

Definitions

Imperfect probability that fathers are investing resources in offspring that carry their own genetic material, as compared to complete female certainty.

Introduction

Paternity uncertainty hypothesis is a construct in behavioral ecology and evolutionary psychology, used to explain differential investment in

offspring between the sexes. The hypothesis states that due to the nature of internal fertilization, a male inseminator cannot be fully assured (consciously or otherwise) of the genetic identity of what are seemingly his offspring. This lack of certainty will further extend to resource and time investment differences between maternal and paternal familial lineages (Buss 2012).

Paternity Uncertainty

Behaviors related to mating and offspring investment should be governed ecologically: an organism will invest energy, time, and resources to promote its own viability and ultimately the continuation of its own genetics. The paternity uncertainty hypothesis states that while the female member of any mating pair can always be 100% assured that her offspring are her own, males enjoy no such guarantee. This is the result of the possibility that the female has been fertilized by one or more *other* males, resulting in paternal, but not maternal, uncertainty. Behavioral strategies to mitigate this uncertainty are not necessarily conscious in nature and should work to diminish the amount of resources accidentally committed to another male's offspring.

The behavioral ecology of mating suggests that each the male and female within a mating pair must consider (in a behavioral sense) the relative costs and benefits of extra-pair copulations. As females stand to gain advantages in genetic material, parental or protective behaviors from alternate males, and other potential favors, multiple mating partners may confer a net gain to them in some circumstances. Conversely, the possibility of female extra-pair copulation confers a potential net loss to the male within the mating pair, namely, the threat that he will unwittingly invest time and resources toward the genetic product of another male. To defend against this, protective behaviors such as mate guarding (Trivers 1972) and offspring identification techniques (Chang et al. 2010) should be seen in species that practice shared offspring investment mixed with promiscuity.

The paternity uncertainty hypothesis further predicts that discrepancies should be seen

between sexes in regard to parental investment, which is the amount of energy and resources devoted by each parent to their offspring (Buss 2012). This should help account not only for the greater investment in resources by mothers but also for discrepancies extending through matrilineal and patrilineal investment rates. As predicted, research indicates that aunts and uncles from the mother's genetic line bestow a greater investment on average than equally distant relatives from the father's family (Gaulin et al. 1997).

These differences in investment represent an extension of Hamilton's rule, which predicts that the degree of relatedness between individuals should correlate with the amount of energy and resources that in individual will grant without expecting reciprocation, outside of benefits to one's own genetic legacy. In the case of paternity uncertainty, the degree of offspring relatedness that any individual on the father's side can assume is slightly diminished. These effects seem to extend to differences in investment by both matrilineal and patrilineal grandparents, where the amount of investment from a maternal grandmother is greater than the maternal grandfather's, paternal grandmother's, and paternal grandfather's, in diminishing order (Bishop et al. 2009).

Differences in behavioral strategies between the mother and father are described in theory and research. Buss et al. (1992) looked at self-reported differences in the causes and levels of jealousy between males and females. Males tended to react more strongly to acts of physical infidelity by their partner, while females were more reactive to emotional betrayal. The authors suggest that this difference is due to males being more threatened by the prospects of raising another male's offspring, while females could lose resources for herself and her offspring as a result of emotional betrayal by the male (i.e., abandonment).

As a result of these risks, researchers have suggested various mechanisms that exist to help reassure the putative father of his paternal certainty. One strategy would be for newborns take on physical characteristics of the birthfather, in order to allay any suspicion of cuckoldry (Daly and Wilson 1982). Others suggest that it is in the interest of newborns to display a nondeterminant

patrilineal identity, so as to avoid rejection behaviors (or worse) from unconvinced fathers. In this model, morphological indices would be replaced by paternity-affirming statements made by relatives, which should help assuage any doubt in the putative father (Bressan 2002). Costs may be incurred by other behaviors as well. Robert Trivers suggests in his book *The Folly of Fools* (2011) that the costs of being temporarily cuckolded may be minor when compared to the personal and social costs resulting from jealous or vengeful behaviors.

Conclusions

Paternity uncertainty is a useful framework for understanding differences between the sexes regarding offspring investment and mating strategies. Other social and cultural influences affect behaviors within individuals; however, unconscious motivations regarding individuals' investment in their own genetic legacy should be reflected in sexual differences in species-specific behaviors.

Pathogen Disgust and Perceptions of Attractiveness

Alec T. Beall

Behavioral immune system; Disgust sensitivity;
Immunocompetence; Pathogen prevalence

Definition

In humans, pathogen disgust is associated with an increased attraction to phenotypic markers of health and genetic fitness.

Introduction

Health and the ability to resist pathogen infection are key to maximizing survival and reproductive fitness, thus humans have evolved to be particularly attracted to phenotypic markers of good health in potential mates (Buss and Schmitt 1993; Rhodes et al. 2005). Some scholars have argued that under conditions of higher pathogen load (real or imagined), attraction to ostensibly healthy potential mates should be amplified and health-connoting characteristics should be preferred (Gangestad and Buss 1993). Mounting recent evidence in support of this increased preference for phenotypic markers of health and immunocompetence has been found at three separate levels of analysis: (1) individual differences in pathogen disgust, (2) temporary salience of pathogen threat, and (3) environmental variation in local ecological pathogen prevalence.

Health and Perceptions of Attractiveness

A wealth of past research points to a link between health and indices of sexual attractiveness. Some studies have found that subjective ratings of attractiveness are associated with judgements of apparent health (e.g., Jones et al. 2004), and other studies have noted a preferential attraction to phenotypic markers of health and immunocompetence such as averageness, symmetry, and gender dimorphism. For example, facial averageness (population-level prototypicality of the face) is associated with strong genetic defenses to pathogens (Thornhill and Gangestad 1993), and average faces (vs. distinctive faces) are consistently rated as relatively attractive (Langlois and Roggman 1990). Similarly, bilateral symmetry, which is associated with fewer in utero infections, and gender dimorphism (i.e., masculinity in men, femininity in women) which is associated with immunocompetence, are two features consistently found to be physically attractive as well (see Rhodes 2006; see also Nedelec and Beaver 2014). This work suggests that perceptions of attractiveness may be guided in part by

phenotypic markers of good health and pathogen resistance.

The behavioral immune system is a suite of psychological mechanisms (including disgust) thought to have evolved in humans to inhibit the spread of disease by steering individuals away from parasitic infection (Schaller and Park 2011). For example, pathogen threat can lead to prejudicial responses against people who possess morphological abnormalities (who may be more vulnerable to pathogen infection), such as the obese (Park et al. 2007). These same cognitive processes may also lead to *approach*-oriented responses toward those who possess qualities of good health and immunocompetence. By seeking out and mating with a healthy partner, individuals may enjoy the direct fitness benefits of reduced risk of pathogen infection, as well as indirect fitness benefits of passing on immunocompetent genes to resultant offspring (Gangestad et al. 2006). Put together, this past work implies that the behavioral immune system may be a driving force guiding preferences for attractive faces and phenotypic markers of health and immunocompetence. If this is the case, then the extent to which perceivers feel vulnerable to pathogen transmission is likely to moderate these attitudinal preferences.

Researchers have investigated whether perceptions of attractiveness are influenced by pathogen disgust and threat of infection and evidence has been gathered at three separate levels of analysis: (1) individual differences in pathogen disgust, (2) temporary salience of pathogen threat, and (3) environmental variation in pathogen prevalence. This evidence is discussed in turn below.

Individual Differences in Pathogen Disgust

The behavioral immune system is not activated with identical frequency and intensity in all individuals; therefore, people vary in their sensitivity to pathogen disgust as well as their perceived susceptibility to infection; this can affect their perceptions of attractiveness and attitudinal preferences for ostensibly healthy individuals.

One prediction implied by this rationale then is that individuals who are more easily disgusted by

pathogens or chronically perceive themselves to be more vulnerable to parasitic infection should hold more negative attitudes against unattractive people. Indeed, correlational evidence suggests that those who are more chronically disgusted by pathogens (but not moral violations or sexual acts) tend to judge relatively unattractive faces as especially unattractive (Park et al. 2012) and those who are more susceptible to pathogen infection during childhood tend to exhibit an exaggerated preference for attractive opposite-sex faces as adults (de Barra et al. 2013).

In addition to an exaggerated preference for attractiveness more broadly, those who are dispositionally more sensitive to pathogen infection may also exhibit a heightened attraction to phenotypic markers of good health and immunocompetence. Indeed, perceived vulnerability to disease is associated with greater attraction to healthy-looking faces and an increased preference for symmetrical faces (Welling et al. 2007; Young et al. 2011). Similarly, trait-level sensitivity to pathogen disgust is positively associated with men's and women's preferences for gender dimorphism (DeBruine et al. 2010; Jones et al. 2013a, b) as well as preferences for lower waist-to-hip ratios and facial cues of lower weight (both indicative of good health; Singh and Singh 2006; Tinlin et al. 2013) in men rating women (Lee et al. 2015; Fisher et al. 2013).

Put together, research suggests that dispositional concerns about pathogens positively predict an exaggerated preference for attractive targets as well as a heightened attraction to health-connoting features more broadly.

Temporary Salience of Pathogen Threat

Perceptual cues indicating the presence of pathogens may temporarily trigger a heightened activation of the behavioral immune system and facilitate situation-specific behavioral avoidance or derogation of those perceived to possess phenotypic markers of poorer health and immunocompetence. Thus, the temporary salience of a parasitic threat or induced feelings of disgust may also affect preferences for attractive targets and phenotypic markers of good health and immunocompetence in ways similar to enduring

trait-level perceptions of pathogen load. Existing research largely supports this prediction.

Burgeoning experimental work suggests that a temporarily heightened concern about pathogens may lead individuals to prefer more attractive targets. Cantú (2013) experimentally manipulated the temporary salience of pathogens (e.g., by having participants read a narrative suggesting incidence of parasitic infection was on the rise vs. reading a pathogen-irrelevant narrative) and examined subsequent preferences for subjectively attractive potential mates. Two experiments revealed that women (but not men) in the “pathogen salience” condition exhibited a stronger preference for physically attractive potential mates. A third experiment revealed that women’s (but not men’s) temporarily heightened concerns about pathogens subsequently lead to faster approach-oriented muscle movements in response to highly physically attractive opposite-sex targets. The effect of temporary pathogen salience may also extend beyond mate preferences into other domains more broadly; for example, following a pathogen threat (vs. a no-threat and a predatory threat condition) individuals were more likely to express intentions to vote for physically attractive rather than relatively unattractive political candidates (White et al. 2013).

Temporary pathogen salience may also play a role in moderating preferences for phenotypic markers of good health and immunocompetence. For example, individuals primed with pathogen threat tend to exhibit preferential attraction to symmetrical and gender dimorphic faces (Young et al. 2011; Little et al. 2011). Other work focusing on women’s preferences has noted a similar pattern of results: The temporary salience of pathogen threat leads women to more strongly prefer masculine men and emphasize qualities indicative of “good genes” (including masculinity) in potential mates (Lee and Zietsch 2011; Watkins et al. 2012).

Put together, this experimental evidence furthers our understanding of how a heightened activation of the behavioral immune system affects perceptions of attractiveness and phenotypic markers of good health. Though these results suggest that temporarily heightened pathogen

concern leads to an exaggerated preference for attractiveness, it is important to note that some experimental investigations have failed to support this prediction (see Park et al. 2012), and more work is needed in this area before firm conclusions can be drawn. Still, when the threat of parasitic infection is salient, a growing body of work suggests that individuals tend to exhibit an exaggerated preference for attractive targets and perceive phenotypic markers of good health and immunocompetence as particularly attractive.

Environmental Variation in Pathogen Prevalence

Especially strong or especially frequent activation of the behavioral immune system among a population of individuals over time could eventually lead to population-level variability in related psychological tendencies and preferences (Schaller 2016). Thus, ecological variability in the actual prevalence of disease-causing pathogens may help to explain cross-cultural differences in perceptions of attractiveness. Specifically, in regions characterized by higher levels of pathogen prevalence, people inhabiting those regions may place a higher value on physical attractiveness or preferentially prefer phenotypic markers of good health and immunocompetence.

Gangestad and Buss (1993) analyzed data from thousands of participants in 29 countries worldwide and found a link between the importance placed on physical attractiveness (i.e., “good looks”) in potential mates and an index of parasite severity. Their results suggest that people in countries with a greater prevalence of pathogens value physical attractiveness in mates more than those in countries with lower pathogen prevalence. Recently this study was revisited, and, even when controlling for additional relevant variables (e.g., gender inequality), the same findings were noted (Gangestad et al. 2006). These results provide robust evidence that regional pathogen prevalence is positively associated with population-level emphasis on physical attractiveness in a mate. Regional variation in pathogen prevalence may also be associated with an exaggerated preference for attractive targets in domains irrelevant to mating as well. For example, during the 2010

US congressional elections, physically attractive political candidates enjoyed greater success in elections held in districts with relatively poorer health outcomes (White et al. 2013).

Regional variation in pathogen prevalence may also play a moderating role in individuals' preferential attraction to phenotypic markers of good health and immunocompetence. Much of this work has focused on women's masculinity preferences and found that women in regions characterized by higher parasite stress and poorer national health more strongly prefer masculine men (DeBruine et al. 2012; Penton-Voak et al. 2004; DeBruine et al. 2010).

Though more work is needed in this area, extant cross-cultural studies suggest that regional variations in pathogen prevalence may also moderate the importance individuals place on attractiveness, as well as phenotypic markers of good health and immunocompetence.

Conclusion

Preferential attraction to phenotypic markers of good health and parasitic resistance appear to be exaggerated under conditions of higher pathogen load (real or imagined). This effect has been noted in (a) individuals who are highly sensitive to pathogens, (b) situations when the threat of pathogen infection is temporarily salient, and (c) regions characterized by high pathogen prevalence and poorer health. Although evidence supporting the link between pathogen disgust and perceptions of attractiveness is becoming increasingly well documented, additional work is needed to further elucidate the intricacies of this relationship.

Definition

The influence of the amount of viruses, bacteria, and other pathogens present in the body on an individual's desirability as a mate.

Introduction

The dominant theory of attractiveness posits that attraction functions as a mechanism for identifying healthy, fertile, appropriate mates. By identifying such high-quality mates, individuals maximize the direct benefits (benefits that accrue

to the individual doing the choosing) and indirect benefits (benefits that accrue to the individual's offspring) available to them and their offspring (Trivers 1972). One such direct benefit is a reduced risk of infection with pathogens or parasites. While a number of studies have linked pathogen load (a measure of the amount of deleterious viruses, bacteria, parasites, and other pathogens in the body) to mate choice in non-human animals, evidence in support of this hypothesis in humans remains more indirect. Here, we define the pathogen load hypothesis, and briefly discuss the evidence.

Immunocompetence Handicap Hypothesis

The need to signal low pathogen load is thought to explain the evolution of extravagant sexual signals in a number of nonhuman species. In order to reliably signal mate quality, it is necessary for a signal to be costly so that it cannot be easily faked (costly signals would place too much of a burden on low-quality individuals). One way in which these ornaments are thought to inflict costs upon the bearer is by placing a burden on the immune system (Hamilton and Zuk 1982), thus ensuring that only individuals with good immunocompetence and low pathogen load can develop such ornaments and maintain good health. Individuals choosing to mate with individuals with more extravagant sexual ornaments may therefore be assured of a high-quality mate.

Male greenfinches with bigger, brighter, sexually selected carotenoid ornamentation show increased humoral immune responses to a novel antigen, more rapidly fight off viruses, and females prefer to mate with males with larger, brighter ornaments (Saks et al. 2003).

Increased pathogen load has also been shown to reduce costly behavioral sexual displays in nonhuman animals. Infection with greater numbers of nematode worms is associated with reduced frequency of courtship displays in male guppies, and females prefer to mate with males with fewer nematode worms (Kennedy et al. 1987).

Human Cues to Pathogen Load

While humans typically lack extravagant sexual ornaments, such as brightly colored feathers, there is evidence that human attractiveness may also partly depend on cues to pathogen load and immunocompetence. Individuals are able to identify sick people based on facial cues such as color of the skin and sclera, and swelling of the face (Axelsson et al. 2018), and on olfactory cues (Regenbogen et al. 2017), leading to avoidance behaviors (Regenbogen et al. 2017). Further, individuals with greater levels of pathogen disgust sensitivity show a stronger aversion to less attractive faces (Park et al. 2012), suggesting that facial attractiveness partly depends on cues to pathogen load.

Moreover, cues that may reflect better immunocompetence, such as facial and bodily symmetry in men and women, and more masculinized features in men (e.g., deeper voice), also seem to be associated with greater judgments of attractiveness (e.g., Feinberg et al. 2008).

There is also evidence that humans moderate their preferences for facial appearance in response to cues to pathogens, with observers showing increased preferences for symmetry and sexual dimorphism (cues thought to reflect immunocompetence and reduced pathogen load) following exposure to cues of high pathogen risk (Little et al. 2011).

Nonetheless, several studies of facial and bodily asymmetry have failed to demonstrate a relationship with health status measures, and even when such relationships are demonstrated, it is important to note that evidence for trait–health correlations now, may not reflect trait–health correlations in ancestral environments (Gangestad 2007).

Conclusion

In sum, pathogen load appears to play a role in mate choice and attractiveness in humans and nonhuman animals, though the precise mechanisms through which this operates are not known.

Definition

The immunologic mechanisms that protect the human subject from microbial, viral, or other organism-derived antigen.

Introduction

In the field of immunology, the study of human pregnancy is perhaps one of the most perplexing topics. A tightly regulated and nuanced balancing act exists between the ability of the maternal host to accept specific foreign paternally derived alloantigens to allow fertilization and support ongoing pregnancy and her need to respond properly to pathogenic invaders, commensals, cell damage, and malignant transformation. The maternal immune system is repeatedly challenged with fetal/paternal alloantigens throughout the

reproductive process starting with exposure to semen, continuing through implantation and placenta-tion, and perhaps lasting several decades after delivery in the form of fetal microchimerism. Likewise, invasion of microorganisms or soluble microbial components into the gestational amniotic cavity can invoke a robust pro-inflammatory response in the fetal environment that can result in pregnancy loss, preterm birth, and neonatal organ damage such as necrotizing enterocolitis, bronchopulmonary dysplasia, retinopathy of prematurity, and cerebral palsy (Anders et al. 2017; Witkin et al. 2011). Inappropriate immune responses in the female regulatory and suppressive responses to both nonself antigens and pathogens could jeopardize the survival of the mother, the fetus, and ultimately the species.

Resistance and Tolerance: An Intricate Dance

Both complex and redundant mechanisms are essential to successfully promote acceptance of the fetal allograft and protect mother and child against pathogens and infection-related inflammation (Hyde and Schust 2016). Defined as the capacity to recognize and neutralize an invading organism, resistance is a means to *prevent* an adverse event. Conversely, tolerance is a mechanism that serves to *negate or minimize the consequences* of an event (Schneider and Ayres 2008).

The presence of circulating antipaternal antibodies in maternal sera at the time of fetal invasion into the maternal decidua was among the first pieces of evidence supporting the concept of maternal tolerance of the fetus (Hyde and Schust 2016). This was a shift from the historical perspective of maternal immune ignorance of paternally derived alloantigens that previously suggested the pregnant woman simply did not recognize the fetus as foreign and therefore did not mount an alloimmune response. In fact, both concepts are partially true, and the dominant response is almost certainly temporally dependent. The maternal immune system must undergo substantial deviations during pregnancy. This

involves mechanisms of at least local immune suppression but also periods of a predominately pro-inflammatory environment, including locally at the time of implantation and both locally and more systemically in the third trimester during preparation for labor (Dekel et al. 2014; Shynlova et al. 2013). To conclude that successful pregnancy is solely based on tolerance versus ignorance of paternal alloantigen or is characterized by an inflammatory versus immunosuppressed state would be an oversimplification. All likely play roles under the constraints of both time- and location-specific parameters.

The fetus must also balance the mechanisms of resistance and tolerance when faced with immunologic challenges. In utero, the fetus cultivates an ability to both recognize invading organisms and produce amplified immune responses to them. This must be balanced, however, by the evolutionary imperative to protect continued reproductive success. The fetal immune response must exhibit an essential capacity to generate tolerance mechanisms that downregulate the extent and duration of most pro-inflammatory states. This serves to both limit the extent of fetal damage and prevent early expulsion of the pregnancy from the uterine cavity whenever possible (Witkin et al. 2011). Some of the earliest evidence of fetal tolerance came from Billingham and colleagues in 1953 when they demonstrated that exposure to foreign antigens in fetal chicks and mice resulted in prolonged postnatal immune tolerance in offspring such that cells able to mount an immune response to these same antigens were absent after delivery.

Immune Structure and Interactions

The immune system is divided into a peripheral compartment, responsible for defense against blood-borne pathogens, and a mucosal compartment, responsible for defense against pathogens that access the body via mucosal surfaces. Not unlike other mucosal sites, the female genital tract acts as the initial barrier and assessor of all antigens, but it is also charged with the task of negatively discriminating against

pathogen-derived antigens while positively selecting tolerance toward seminal and fetal antigens (Hyde and Schust 2016). Strong hormonal control of the female genital tract aids in the tolerance of specific nonself antigens by affecting immunoglobulin transport, antigen presentation, cytokine levels, and distribution of immune cell populations. Estrogen, progesterone, and hCG have each been shown to promote immunologic changes that support maternal tolerance of fetally derived alloantigens, including the development of maternal T-helper 2 cell immune responses, the maintenance and expansion of maternal T regulatory cells, and the creation of anti-inflammatory cytokine environments, both locally and systemically (Hyde and Schust 2016).

Although far beyond the scope of this document, some of the most important immunologic mechanisms involved in fetal tolerance and pathogen protection are the unique immune cell types known to populate the female reproductive tract. In contrast to cells present in mucosae at other locations in the body, immune cells in the female reproductive tract are in contact with placental trophoblast cells singularly characterized by alterations in major histocompatibility complex (MHC) expression that allow prolonged and direct exposure of maternal immune cells to HLA-mismatched gestational tissues (Hyde and Schust 2016). Further, animal studies have demonstrated that there is a pregnancy-specific, local partial deletion of those maternal B cells that are directed against paternal antigens within the uterine decidua of the maternal-fetal interface. Significantly more antibody-producing cells can be found in the lower genital tract of the pregnant woman (endocervix > ectocervix > vagina) to maintain mucosal pathogen surveillance (Aït-Azzouzene et al. 1998). Decidual stromal cells are also immunologically unique and have recently been shown to respond to diverse bacterial and viral ligands that could cause placental inflammation (chorioamnionitis) and subsequent adverse outcomes such as preterm birth, neonatal sepsis, and cerebral palsy (Anders et al. 2017). In addition to their role in pathogen protection, decidual stromal cells are best known for their role in the immune acceptance of the allogeneic

fetus. They aid in the transformation of the uterine environment into a receptive implantation site, and they decrease the proliferation of certain natural killer (NK) cells and antigen-presenting cells that may stimulate attack of the implanting gestation. Other unusual immune cells specific to the female genital tract include decidual natural killer (NK) cells, decidual NKT cells (cells that exhibit characteristics of natural killer and T cells), decidual macrophages, T cell receptor (TCR) $\gamma\delta^+$ cells, and other less numerous innate lymphoid cells (Hyde and Schust 2016). Decidual NK cells differ from their peripheral counterparts in their cell surface receptor expression and in their poor killing activities. Unlike their peripheral and tissue-resident counterparts, decidual macrophages have cytokine secretory profiles that are skewed toward anti-inflammatory, M2-type activities.

Lastly, several contributions from the male partner have also been shown to be important for the success of fertilization and reproduction. One of these, termed “the leukocyte reaction,” is a semen-induced change in gene expression in the female reproductive tract that results in the presentation of pro-inflammatory antigens and recruitment and activation of immune cells necessary for fetal tolerance (Sharkey et al. 2012). Sperm lack major histocompatibility complex (MHC) class I and II molecules (transplantation alloantigens) on their surface. This allows them to avoid stimulation of specific histocompatibility-based adaptive responses in the female genital tract. Additionally, seminal fluid provides protection of sperm from reactive oxygen species that may be formed in response to an infectious agent (Hyde and Schust 2016).

The Fetal Role: An Active Player

Notably, it is now acknowledged that the fetus is an active participant in the immunologic interplay within the maternal reproductive tract, promoting tolerance of itself while simultaneously maintaining protection from microbial intruders. In early pregnancy, the main focus of the fetus is to promote tolerance. However, as the fetus nears delivery, an essential change from fetal

protolerogenic responses to pathogen-defensive, adult-type immune responses must take place so that the newborn is equipped to respond to outside invaders. This novel model of the fetal immune response across pregnancy has been called the layered immune system hypothesis (Burt 2013).

For example, although fetal immune cells can discern foreign pathogens, during the majority of pregnancy, there is a tendency for fetal T cells to differentiate toward T regulatory cells that promote a protolerogenic environment (Witkin et al. 2011). Further, a fetus challenged by pathogenic intruders appears to have an enhanced capacity to tolerate some level of local infectious stimuli, which diminishes its exposure to toxic immune by-products that would accompany microbe elimination and lessens the likelihood of premature delivery due to overly robust immune activation. One such mechanism involves the triggering of certain Toll-like receptor (TLR)-initiated pathways that promote the accumulation of specific lipopolysaccharide (LPS) – binding proteins and antimicrobial peptides (Witkin et al. 2011).

Later in gestation as the fetus matures and approaches delivery, its immune cells undergo transition to phenotypes more typical of adults, including the development of fetal memory T cells (Burt 2013; Zhivake and Lo-Man 2017). It is postulated that in this “layered immune system,” the *fetal tolerogenic* T cells are derived from *fetal* hematopoietic progenitor stem cells (HPSCs) and comprise the majority of the fetal immune system until late in the third trimester. At this point, fetal immune responses transition toward one dominated by *adult immunogenic* T cells derived from *adult* HPSC. This transition allows the fetus, and soon to be newborn, to have an adequate protective immune response to a wide variety of extra-uterine pathogens (Burt 2013).

Conclusions

The ability to fully understand and elucidate the immunologic nuances at the human maternal-fetal interface is hindered by the time- and location-specific nature of these interactions. Furthermore, many studies rely on evidence derived from

animal models due to logistical and ethical confines on human studies that are non-negotiable. Differences found in the human placenta, such as the high degree of placental invasion when compared to other species, limit the information that can be ascertained by even the most rigorous animal studies. The essential balance between pregnancy maintenance and pathogen protection involves numerous complex and overlapping immunologic mechanisms. It is only through a delicate interplay of alloantigen tolerance and maintenance of a robust ability to resist pathogen invasion that the human species is able to propagate into the future.

Pathogen Resistance

Sarvodaya Tripathy

Department of Microbiology, M.K.C.G. Medical College, Brahmapur, Ganjam, Odisha, India

Synonyms

Microbial resistance

Definition

It is the resistance developed by the pathogen to survive in adverse host environment.

Introduction

Pathogens are microscopic organisms which can cause infectious diseases in other species. Pathogens that can cause human diseases are bacteria, viruses, fungi, and parasites (Janeway et al. 2001). There occurs continuous interaction of pathogens with their hosts in a given environment. As the host develops immunity to the pathogen (which is essential for host survival), the pathogen also parallelly develops resistance to overpower the host defenses. Evidences support that with the advent of chemical agents, intended to kill the pathogens and protect the host, there occurs emergence of resistant strains of pathogens (Narayanasamy 2008).

Pathogen Resistance: Evolutionary Perspectives

In the process of evolution, pathogens acquire features, which make them fit for their

environment. A survival need of any organism, is to remain fit in the adverse environment. Pathogens, for example, may develop mechanisms, to evade the immune system of the host and to resist the adverse effects of drugs in their vicinity. Thus, development of resistance gives an evolutionary advantage to the pathogens.

Evolutionary potential of pathogens may vary. Pathogens having high evolutionary potential are capable of overcoming genetic resistance quickly. They have higher mutation rates and have mixed reproductive system. Pathogens with low evolutionary potential have difficulty in overcoming genetic resistance. They have lower mutation rate and strict asexual reproduction (McDonald and Linde 2002).

In the environment, the pathogen and host evolve concurrently. The host also develops resistance to counter the spread of infection and tolerance to limit the after effects of infection (Roy and Kirchner 2000). Both the phenomenon of resistance and tolerance can propagate through genetic mechanisms.

Evasion of Host Immunity by Pathogens

Microbes have developed mechanisms to avoid or resist the action of host immune system. Some bacteria develop capsule (e.g., pneumococcus) which prevents adhesion to leukocytes, and some may produce exotoxins (e.g., diphtheria toxin) which are harmful for the leukocytes. Other examples include M-protein of *Streptococcus pyogenes* which reduces the complement activity. Certain bacteria (*Mycobacterium*) and fungi (*Histoplasma capsulatum*) survive intracellularly in macrophages, thus avoiding the humoral immune system (Delves et al. 2006). Fungi can inhibit intracellular killing by blocking intracellular respiratory burst. This is done by producing catalase, mannitol, and melanin. Fungal proteases can prevent the destruction of conidia inside macrophages. Viruses avoid the immune system by changing their surface antigens. Budding virions can laterally invade surrounding cells without becoming exposed to antibodies. Viruses can interfere with almost step in antigen

processing by host immune system. *Trypanosoma cruzi* the parasite responsible for Chagas disease has developed a DAF (decay-accelerating factor)-like molecule which breaks the complement factor C3b. *Trypanosoma brucei* releases decoy proteins to hide itself from the immune system. In malaria caused by *Plasmodium falciparum*, erythrocyte membrane protein 1 (PfEMP1) expressed on cell membrane of infected RBC helps the parasite to clump RBCs and spread without getting much exposed to the immune system. Some parasites avoid being recognized by the immune system by molecular mimicry with host tissues (e.g., *Ascaris* antigens mimic human collagen). Schistosomes cover their surface with host proteins like RBC glycoprotein and immunoglobulin G (Delves et al. 2006).

Resistance Against Antimicrobial Drugs

With the introduction of antibiotics, it was initially believed that infectious diseases would no longer pose a problem. Bacteria have, however,

gradually developed mechanisms to counter the effect of antibiotics on themselves. Due to injudicious use of these so-called magic drugs, multiple drug-resistant strains of almost all known bacterial pathogens have developed. Infections caused by these strains are very difficult to treat and responsible for very high mortality. Gradually there occurred emergence of “super-resistant bugs,” and dealing with them has become the biggest challenge for present medical science. Superbugs are strains of microbes with an increased level of resistance or resistant to multiple antibiotics. Table 1 shows common mechanisms by which bacteria generally acquire resistance to antibiotics.

β-Lactam antibiotics include penicillin and related drugs; cephalosporins, monobactams, carbapenems, etc. are the most widely used group of antibiotics. β-Lactam antibiotics act by inhibition of bacterial cell wall synthesis. Bacteria developed resistance to these antibiotics by producing β-lactamase enzymes, which dissociate β-lactam ring of the drug. For example, penicillinase enzyme was able to make the earlier

Pathogen Resistance, Table 1 Mechanism of drug resistance of bacteria against different antimicrobial agents

Mechanism of resistance	Example of antimicrobial class	Specific mechanism	Example
Efflux of the drug	Macrolides (erythromycin, azithromycin)	Efflux pumps pump the drug out of cell	Streptococci, staphylococci
Decreased uptake of the drug	Quinolones (ciprofloxacin, levofloxacin)	Altered outer membrane	Gram negative bacteria
	Aminoglycosides (amikacin, gentamicin)	Altered porin channels	Gram negative bacteria
Altered target of drug	β-lactam antibiotics (penicillin, piperacillin, cefuroxime, imipenem)	Altered PBP due to chromosomal mutation	MRSA
	Quinolones	Mutation in subunits of target DNA gyrase	Gram negative and gram positive bacteria
	Glycopeptides (vancomycin)	Production of altered cell wall precursors	VRE, VRSA
	Aminoglycosides	Mutations in ribosomal binding sites	Enterococcus
Enzymatic degradation of the drug	β-lactam antibiotics	Destruction of β-lactam ring	<i>S.aureus</i> resistance to penicillin, ESBL produces among gram negative bacteria
Enzymatic modification	Aminoglycosides	Aminoglycoside modifying enzymes	Gram negative and gram positive bacteria

PBP penicillin binding protein, MRSA methicillin resistant *S. aureus*, VRE vancomycin resistant enterococci, VRSA vancomycin resistant *S. aureus*, ESBL extended spectrum β-lactamase

generation of penicillin ineffective. Penicillinase-resistant β -lactams (e.g., methicillin, oxacillin) were developed. These drugs act by inhibiting the cross-linking between the peptidoglycan chains of bacterial cell wall. They bind and competitively inhibit the transpeptidase enzyme (penicillin-binding protein (PBP)). Bacteria have developed resistance to these antibiotics too. They have altered the target to form PBP2a, in place of its normal counterpart. PBP2a is coded by *mecA* gene carried on a mobile genetic element (*SCCmec*) (Peacock and Paterson 2015) in *Staphylococcus aureus*. PBP2a have low affinity for β -lactam antibiotics, and thus cell wall synthesis proceeds without much problem for the bacteria. Another very important mechanism of antibiotic resistance is production of extended spectrum β -lactamases (e.g., ESBLs) which are a group of plasmid-mediated enzymes (Rawat and Nair 2010). ESBLs are resistant to extended-spectrum (second- and third-generation) cephalosporins which include cefotaxime, ceftriaxone, and ceftazidime and monobactams like aztreonam. Multidrug-resistant *Salmonella enterica* is resistant to chloramphenicol, ampicillin, and sulfamethoxazole. Extensively drug resistant (XDR) in *Salmonella enterica*, serovar Typhi has been reported to show plasmid-encoded resistance to fluoroquinolones and third-generation cephalosporins (Klemm et al. 2018).

Polymyxin antibiotics (polymyxin B and colistin) are last-resort antibiotics for multidrug-resistant gram-negative bacteria. Bacteria like *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, and *Acinetobacter baumannii* have already developed resistance to these antibiotics, by various mechanisms like lipopolysaccharide modifications, efflux pumps, and overexpression of the outer membrane protein (Olaitan et al. 2014).

Resistance in hospital settings – infections that occur after 48 h of hospitalization – is referred to as nosocomial infections. Multidrug-resistant bacterial strains like MRSA and ESBL producers are common in hospital settings because of more environmental pressure. Transmission of the genes of resistance to sensitive bacteria also occurs. Three different mechanisms of horizontal

gene transfer, namely, conjugation, transformation, and transduction, are mainly responsible for transmissible drug resistance.

Intrinsic resistance to specific antibiotics is shown by certain bacteria. Intrinsic resistance is natural and predictable in bacteria like- *Klebsiella* to ampicillin, anaerobes to aminoglycosides, and *Burkholderia* to polymyxin B (Tille 2016). Keeping a track of the intrinsic resistance profile of causative bacterial pathogen is important to avoid development of resistant strains of other bacteria in the vicinity. Deciding the antibiotics after performing antibiotic susceptibility test, proper dosage and complete course of drug in the correct patient can help us to curb the spread of drug resistance.

Resistance Genes from Food

Sub-therapeutic levels of antibiotics like penicillin and tetracycline – are being given, since the mid-1950s, to animals to increase feed to weight ratio. They were then called antimicrobial growth promotants. Other reasons for which antibiotics are used in animals include disease treatment and prevention. These antibiotics were also used in agriculture industry (Marshall and Levy 2011; Verraes et al. 2013). Food processing can also add resistant bacteria to the food chain, i.e., certain bacteria that are intentionally added during the processing of food. Microbes added to foods requiring fermentation (e.g., *Lactobacillus*, *Leuconostoc*), addition of probiotics (e.g., *Saccharomyces*), and biopreservation where microorganisms are added to extend the shelf life and bacteriophages are used to kill foodborne pathogens (like *Salmonella enteritidis*, *Campylobacter jejuni*) (Verraes et al. 2013).

Antibiotic resistance in *Mycobacteria* occurs by vertical gene transfer, i.e., transmission of mutated gene to progeny. Mechanism of action of rifampicin, which is one of the most effective drugs against *Mycobacterium tuberculosis*, is binding to the β -subunit of the RNA polymerase enzyme, inhibiting the elongation of messenger RNA. β -Subunit of the RNA polymerase enzyme is coded by *rpoB* gene whose mutations lead to

rifampicin-resistant strains (Palomino and Martin 2014). Isoniazid, another common drug used in tuberculosis, is a prodrug. It requires activation by the catalase/peroxidase enzyme encoded by *katG* gene. It inhibits the synthesis of mycolic acids through the NADH-dependent enoyl-acyl carrier protein (ACP) reductase, encoded by *inhA*. Resistance to isoniazid occurs due to mutations in *katG* and *inhA* genes among other genes. Multidrug-resistant isolates of *M. tuberculosis* are resistant to both these drugs. Many other mutations causing resistance to different first- and second-line antimycobacterial agents are known. Newer drugs like bedaquiline and delamanid have also started showing resistance mutations (Palomino and Martin 2014).

Antiviral drugs are increasingly prescribed to counter viral infection due to immunosuppressive treatment in patients of transplantation, graft-versus-host disease, etc. Also, in PLHA (patients living with HIV and AIDS), antiviral drugs are to be taken for prolonged period. Prolonged exposure to antiviral drugs with continuing viral replication, owing to immunosuppressive state, is the key factor in the development of antiviral drug resistance in these patients (Strasfeld and Chou

2010). A major concern is treatment failures due to development of antiretroviral drug resistance in PLHA patients. Structural modification caused in antiretroviral target molecules of HIV occurs due to genomic mutation. Reverse transcription process is error-prone, and thus there is increased rate of mutation in HIV virus, leading to increased chances of survival of the virus in the patient.

Most common fungal pathogens encountered in clinical settings are *Candida* and *Aspergillus* species. A wide spectrum of antifungal agents is currently available including triazoles, echinocandins, polyenes, and allylamines. The choice of suitable antifungal agents however remains limited due to the emergence of resistant fungal species. There can be more than one mechanism of resistance development against a group of drugs, as shown in Table 2 (Chakrabarti 2011; Cowen et al. 2015; Ghannoum and Rice 1999; Peman et al. 2009).

Biofilm production by various bacteria, mycobacteria, and fungi imparts capability of drug resistance to the microbial colony (Donlan 2001; Esteban and García-Coca 2018). Recently, it has been seen that human T-cell leukemia virus-1 (HTLV-1) gets embedded in

Pathogen Resistance, Table 2 Mechanisms of resistance to antifungal agents

Group of antifungal examples	Mechanism of action	Most important mechanisms of resistance
Polyenes Amphotericin B Nystatin	Bind to ergosterol in the plasma membrane causing formation of large aqueous pores that disrupt cell	Altered membrane ergosterol synthesis ERG3 gene defects
Triazoles Fluconazole Itraconazole Voriconazole	Inhibition of ergosterol biosynthesis	Activation of efflux pumps Decreased affinity to target site <i>ERG11</i> and <i>Cyp51A</i> genes Overexpression of <i>ERG11</i> gene in <i>Candida</i> and <i>Cyp51A</i> in <i>Aspergillus</i> Impaired drug penetration
Echinocandins Caspofungin Micafungin	Inhibition of biosynthesis of β -1,3-D-glucan which is a major structural component of the fungal cell wall	Point mutations in <i>FKS</i> genes of target enzyme β -1,3-D-glucan synthase
Allylamines Terbinafine	Inhibition of ergosterol biosynthesis	Not yet documented, (cross-resistance with fluconazole reported)
Flucytosine 5-fluorocytosine	Inhibition of pyrimidine metabolism and DNA synthesis	Alteration of enzymes- Cytosine permease coded by <i>FCy2</i> gene Cytosine deaminase coded by <i>FCy1</i> gene

carbohydrate-rich adhesive extracellular “cocoon” (similar to biofilms) that helps efficient and protective transfer of virus between cells (Thoulouze and Alcover 2011).

It is difficult to develop immunity to parasitic infections because of their enormous variation in size, complex life cycle, and multiple hosts in different stages of life cycle. Parasite-causing malaria, *Plasmodium falciparum* species mainly, has evolved to develop several mutations to counter the antimalarial drugs. Drug resistance mutations in *P. falciparum* include point mutation in *Pfprt* gene, *Pfmdr1* gene, *Pfmrp* gene, *Pfdhps* gene, *Pfdhfr* gene, etc. To curb drug resistance due to antimalarial monotherapy, artemisinin-based combination therapies (ACTs) were started. Recent reports of resistance to artemisinin due to polymorphism in Kelch13 protein from Southeast Asia have raised alarm against successful treatment of malaria (Antony and Parija 2016).

Conclusion

Development of resistance by the pathogens is crucial for their survival. During the process of evolution, the host defense system develops against pathogens, and simultaneously the pathogens develop resistance to antimicrobial agents and host immune system. Understanding pathogen resistance gives insight about the evolution of the pathogens.

Definition

Pathogen risk refers to the danger presented by microorganisms that cause disease.

Introduction

There is a clear evolutionary opportunity for a pathogenic or parasitic existence, living at the expense of nutrient-rich, warm, renewable hosts. These advantages are reflected by the number and variety of infectious organisms that are pathogenic to humans alone, with a comprehensive literature review identifying 1415 species (Taylor et al. 2001). These pathogens can be divided into five major taxonomic divisions: 15% are viruses (including prions), 38% bacteria (including rickettsia), 22% are fungi, 5% are protozoa, and 20% are helminths (Taylor et al. 2001). To further illustrate the appeal of a host environment, nonpathogenic bacteria (distinguished from pathogens by lack of host-damage) far outnumber human cells within our bodies (Rohmer et al. 2011). While nonpathogenic bacteria are tolerated by hosts, pathogenic organisms are exploitative and so have to overcome host defenses. These include specific evolved mechanisms, such as toxic compounds, which can function defensively or offensively by manipulating or destroying rival microbes and host immune defenses (Rohmer et al. 2011; Rudkin et al. 2017). However, many of these mechanisms cause damage to and risk killing the host. This means there is an evolutionary trade off that every pathogen must contend with; just as there is no advantage to be unable to colonize or to be killed by the host’s defenses, it is of no advantage to be so lethal that you kill the host before you have a chance to benefit from the environment, replicate, and spread to other hosts. How each species contends with this trade-off is different, for example, lethality and host damage matter less for bacteria that are able to survive longer outside the host, or after the host has died, or can transmit to new hosts rapidly (Rudkin et al. 2017).

Just as there are clear evolutionary advantages for pathogens to live at our expense, it is equally advantageous for animals to develop systems to defend against pathogens. Communicable diseases caused by pathogens present a significant risk to human health and life and, despite deaths caused by certain communicable diseases having lessened in the past 100 years (recently, for

example, death by diarrheal diseases decreased by one million between 2000 and 2016), they remained as 3 out of the top 10 global causes of deaths in 2016 (diarrhea, tuberculosis, and lower respiratory infections). To illustrate the scale of this risk: the deadliest communicable diseases – lower respiratory infections – caused three million deaths worldwide in 2016 (WHO 2018). Further to the risk from existing pathogenic microorganisms, there is an ever-present risk of newly emerging pathogens, as 335 new infectious diseases have been reported since 1940 (Fumagalli et al. 2011; Taylor et al. 2001). These emerging infections are almost always caused by an existing pathogen that adapts to a new host. For example, the HIV virus previously infected chimpanzees and Ebola was previously found in bats (Sironi et al. 2015). There is also an evolutionary asymmetry to consider; humans have both far longer life spans and smaller populations than pathogens, meaning we evolve at a slower rate (Sironi et al. 2015). So, humans are faced with the threat of a wide variety of fast-evolving pathogens which are able to emerge as new threats from different host species.

Physiological and Behavioral Immune Systems

We are thought to manage the risks presented by pathogens first with our internal, physiological, immune system and second with a psychological, behavioral defense system. First, our physiological immune system uses two branches of defense, the innate immune system and the adaptive immune system. These two branches are primarily differentiated by mode of activation; the quicker but more primitive innate immune system relies on predetermined pattern recognition of abnormal, foreign bodies whereas the slower but more flexible adaptive immune system requires prior exposure and thus relies on specific recognition and immunological memory (Rohmer et al. 2011). Both systems are required for an effective response; emerging or unfamiliar pathogens must be dealt with quickly using the innate immune system, which can expel or hold the

pathogen at bay until the adaptive immune system can develop a more sophisticated, tailored response.

The second system for reducing pathogen risk, based around psychological and behavioral defenses, offers the advantageous outcome of avoiding infection completely. Aside from the obvious risk that our immune system could be bested by invaders, fighting off infection is debilitating (even if just temporarily) and metabolically costly (Schaller 2011). Therefore, it is thought that humans also possess what is termed the *behavioral immune system*, which was coined to capture the apparent unified functioning of specific behaviors and cognition that work to reduce the risk of infection (Schaller 2011). It is proposed that this system responds to various environmental cues, such as unpleasant odors, that tend to co-occur with pathogens, and triggers the disgust emotion. This disgust reaction encourages either withdrawal, for example, through feelings such as nausea, or pathogen-removal behaviors, such as vomiting, washing, and spitting. This helps us avoid objects, animals, and even people that may pose an infection risk. However, just as the physiological immune system has costs (such as metabolic expense) as well as benefits, as does the behavioral immune system. The avoidant responses of the behavioral immune system can stand in the way of other fitness relevant goals, for example, by encouraging avoidance of social or mating opportunities because of the possibility they carry some infection risk (Schaller 2011). As such, the individual sensitivity of our behavioral immune system is another trade off which we must contend with.

Psychological Consequences of Pathogen Risk

Although all humans are at risk from pathogens, it seems likely that there is variability in the sensitivity of the behavioral immune system between individuals, both at a trait level and dependent on current pathogen risk. First, we can infer trait level differences in an individual's behavioral immune system from measures of

disgust sensitivity (which measures our natural predisposition to feel disgusted). These individual differences can have far reaching consequences for our behavior, for example, those who are highly disgust sensitive are more likely to be politically conservative (Inbar et al. 2009), differ in mate choice (Gangestad et al. 2006), and display harsher moral judgments (Chapman and Anderson 2014). This pattern of behavior suggests that those who are more disgust sensitive are more avoidant of those who are perceived to be potentially infectious or harmful.

An interesting example of how disease burden has influenced our psychology is differences in disgust sensitivity and ingroup bias. Interpersonal contact with unknown others would expose an individual to unencountered, dangerous, pathogens. As such, it is clear that there is a connection between ingroup bias and disgust, for example, participants were less disgusted by clothing worn by a member of their University (Reicher et al. 2016) and disgust sensitivity predicts dehumanization of arbitrary outgroup (Buckels and Trapnell 2013). This effect can also be seen temporarily in those who are at greater risk of infection, for example, women in their third trimester of pregnancy displayed elevated levels of ethnocentrism (Navarrete et al. 2007).

We can also use the example of ingroup bias to show that some cultural differences could be linked to differences in disease burden between cultures. Pathogen risk varies across cultures, both historically and in the present day. When controlling for demography, selection pressures imposed by variation in pathogenic load explain much genetic variation between populations and is thus argued to be the primary driver of local adaptation (Fumagalli et al. 2011). Aside from genetic variation, it has also been demonstrated that countries with a historically high disease burden are more likely to be collectivist (Fincher et al. 2008). The reason for this difference is hypothesized to be due to collectivist cultures having a stronger ingroup-outgroup differentiation which, as discussed above, would limit exposure to new pathogens (Jetten et al. 2006). In further support of this, it seems that individualistic cultures were subjected to a higher

number of infectious disease outbreaks between 1950 and 2008 than collectivist cultures (Morand and Walther 2018). So, it seems that historically high pathogen risk may influence the psychology of a culture as well as providing some protection from infection.

Conclusion

It is not surprising that pathogens wish to benefit from the human body as it is an attractive ecosystem which at any time is home to thousands of microbial species, most of which rarely (if ever) cause us illness. Access to the rich diversity of nutrients within animal tissues is worth competing for, and as such dedicated pathogens have developed mechanisms that aid them in colonizing and replicating within host bodies. This is no easy task as humans have both psychological and immune defenses which exist to avoid, destroy, or expel viruses and infected somatic host cells. This competition to invade and avoid invasion exerts selection pressures on both organisms. As such, pathogen risk has far-reaching consequences for the virulence of the pathogens themselves, human biology, and both individual and cultural psychology.

Patriarchy and Feminist Perspectives

Mariana Costa Biermann and Mariana Gonçalves Farias
Federal University of Ceará, Fortaleza, CE, Brazil

Synonyms

[Feminist waves](#); [Male social dominance](#)

Definition

A system of gender-based hierarchy in which men hold primary power. Feminist perspectives are related to the feminist movement based on the social, political, and economic equality of the sexes.

Introduction

During human evolutionary history, as also nowadays, most societies operate on a hierarchical system of organization. Patriarchy is an example of a hierarchical social system in which power is held by men based on male dominance in social, legal, religious, economic, and political organization (Sultana 2010).

The emergence of dominance hierarchies is not an aspect restricted to the human species but widely observed in nature (Buss 2015). Nonetheless, the environmental contexts of ancestral humans were far more hostile than in modern society. Therefore, ancestral contexts would create adaptive problems that could be successfully solved with conducts that are currently socially disapproved, such as aggressiveness and violence. For example, the use of force was a successful way of gaining social dominance by solving a conflict of interests and establishing a hierarchy (Buss 2015).

Denise Cummins (1998) developed the Dominance Theory, which primarily addresses the evolved ability to create strategies to reason about social norms (e.g., permissions, prohibitions, and obligations). The ability to strategize over social norms would enhance the reproductive fitness of the individual and, therefore, privilege those individuals that aspire to dominant status. Children in early life can already discriminate what is socially accepted, what is forbidden, and what is an obligation; acting accordantly with these social norms would consequently enhance the status quo of the individual in the group (Cummins 1998). For example, a woman adapted to a patriarchal context would behave accordantly with the obligation of being a good wife and mother, as well as the clear comprehension that she has not the permission to achieve an economic and political position of power designated for men. Due to the established adequate behavior, that woman would be a high-quality partner, and, hence, be able to access resources necessary for survival by mating with men of high status in hierarchies.

Male Dominance and the Origins of Patriarchy

Men and women present different mating strategies, however, they need each other to reproduce. Hence, survival and reproductive success are intrinsically affected by interpersonal relationships between men and women (Buss 2015; Parker 2006).

The conflict between the sexes over sexual strategies is a central topic in human social relations, and, therefore, human social organization. Males and females present different reproductive interests, which causes a conflict. Due to this conflict, men often gain access to females by coercive sexual strategies, which leads to the men's control over women.

The fundamental limitation in achieving reproductive success is access to a mate (Mesnick 1997). This limitation impacts directly on male mating strategies, creating a sexual conflict motivated by the asymmetry of interests between a man and a woman (Buss 2015). Historically, males have gained control of important resources to survival, such as food, shelter, and protection. This control forced women to submit to male mating interests so they could have access to resources for themselves and their offspring (Buss 2015). While coercive strategies were used by males to maintain control over women, the submissive position also had fundamental functions on the course of evolutionary human history, establishing survival and reproductive advantages for both sexes (Buss 2015). Nonetheless, the inflexibility of this social configuration and the coercive male dominance assumed an oppressive organization, thus preventing most women from achieving social, economic, and politic power that was not seen as proper for females. For example, male control over resource was maintained in society by legacies that neglected women and privileged male heirs, e.g., a direct son or a husband to a man's daughter (Alston 2012; Cooper 1976; Michaelson and Goldschmidt 1971). This control represents a system of gender-based hierarchy, in which men hold primary power – the Patriarchy. Therefore, over the centuries, women were socially

disadvantaged and mostly needed a male partner to be able to achieve some social power.

Therefore, Patriarchy established female biological inferiority, as well as evolved psychological mechanisms that would maintain male dominance. For example, the human species demonstrates an unusual male control over female sexuality, establishing a socially appropriate behavior for women (Smuts 1995). This moral stigmatization by men of adequate behavior for the female sex and what woman can do created a based-gender hierarchical organization in human society.

Feminist Perspectives: Female Resistance as a Threat to Patriarchy

Feminism movement represents the battle for the social, political, and economic equality of the sexes in a patriarchal society. However, this movement, despite posing gender as a central issue, does not have one singular and uniform perspective, but a wide variety of feminist perspectives, which impacts on science and, specifically, on evolutionary research (Rosser 1997). For example, the appearance of the Liberal Feminism, a theoretical perspective initiated in the eighteenth century and based on the scientific comprehension that human behavior is highly individualist and needs to be researched with a positivist approach (Jaggar 1983).

Moreover, this theoretical perspective assumes that women are socially oppressed by male dominance and, therefore, are victims of gender discrimination in the different fields of society (Rosser 1997). For example, studies suggest that the impact of the asymmetrical opportunities for men and women in modern society depends on lower access to resources for women to education and work opportunity (Arráiz 2018). In addition, Rosser (1997) indicates that the scientific field is mostly dominated by men, which represents that data interpretations are shaped by a subjective male point of view, despite the neutrality intrinsic to the scientific method.

The liberal feminism perspective also states that the opportunity gap has been legitimized

by science on the basis of research focusing primarily on the male perspective on evolutionary research, as well as excluding female subjects in experimental research or even by data interpretations based on patriarchal standards (Rosser 1997). Despite the relevance of questions elaborated by the liberal feminists, this perspective is committed to a capitalist economic structure and thus neglecting aspects of women's oppression not discussed at the time (Waites 2018). Therefore, postulations of liberal feminism only began to highlight the barriers that prevent women from having the same opportunities as that of men, enhancing the chances of overcoming those barriers, as well as questioning the objectivity of the scientific method on the matter of gender biases (Rosser 1997).

In contrast to Liberal Feminism, a perspective embedded in capitalist principles, Socialist Feminism rouses from Marxist ideology (Rosser 1997). Against the idea that scientific knowledge should be approached by individualistic and positivistic methods, Socialist Feminism assumes that knowledge is socially constructed and that the economic system of production influences how research is made (Rosser 1997). The socialist feminist theory states that female oppression should be addressed through an intersectional perspective, considering gender and economic class as social categories that due to their interaction form different configurations of oppression for women (Misra 2018). Therefore, patriarchy and capitalism would represent the social, political, and economic systems of a social organization responsible for maintaining a context of oppression for women (Burrell and Flood 2019).

However, this theory comprehends men and women differently in a biological and a social perspective, which would be explained by different evolved behaviors and psychological mechanisms (Arráiz 2018). Therefore, the socialist feminist perspective proposes the enhancement of female participation in science since the female point of view could reach a closer interpretation of reality, providing a contrast to the knowledge produced by a male scientist (Rosser 1997).

While Socialist Feminism assumes class as an intersectional category with impact on women's

oppression, African-American Feminism identifies race as a fundamental aspect that influences the approach to knowledge by science (Rosser 1997). Maintaining the intersectional perspective and the rejection of the individualism and the positivist approach to science, African-American Feminism began to gain force in the feminist movement and in science.

In addition, once the scientific knowledge is assumed incapable of complete objectivity and neutrality, it would be influenced by the white male scientists' point of view, representing the prevailing interests of the dominant race, class, and gender (Rosser 1997). Therefore, this perspective proposes not only the enhanced participation of black and Latina women in the scientific field, but a whole new configuration on the science discourse and methodology, providing a more critical decolonial data interpretation (Kelly and Jackson 2019).

Another feminist perspective is Radical Feminism, similar to the socialist feminist perspective on the critique to the social, economic, and political organization. This perspective does not rely on identity-specific aspects (e.g., race or class), but in the strong ideology that patriarchy and capitalism are the fundamental reason for women oppression (Waites 2018). Specifically, it emphasizes the more hostile and violent aspects of male oppression toward women, in which are more visible the asymmetrical relations of power between the sexes (Finlayson 2016), such as prostitution, rape, and pornography (Waites 2018).

In modern society, a discourse that the feminist movement was contributing to emasculate men began to gain activists using arguments based on deterministic social sex roles. Within the feminist movement, the diversity of approaches brought the fragmentation of feminism in plural discourses, emphasizing different aspects of women's oppression and dividing women (Cree and Phillips 2019). The postmodern feminist perspective emerged as a response to the propatriarchy movement, focusing on the critique of essentialist aspects of female and male identity categories, and, hence, breaking with a deterministic social sex role for men and women (Cree and Phillips 2019). Therefore, rejecting a discourse on

behalf of women, and collaborating to a more inclusive and non-fragmentized feminism, in which all women share gender as an identity aspect, but not neglecting individual traits that increase or minimize oppression, such as economic class and race (Rosser 1997).

The Darwinian Feminism

Evolutionary theory has been used for decades to legitimize a perspective of female inferiority, and therefore, creating biological arguments that maintained the subordination of women through human history (Vandermassen 2008). Those oppressive arguments were based mainly on the study of similarity between human and other primates behaviors' topography. However, the same perceived behavior in different species does not necessarily indicate the same function and the same genetic origin (Tang-Martinez 1997).

Thus, the feminist movement was severely harmed by false scientific arguments that postulate the patriarchy as inevitable. Due to a biological explanation, the evolutionary perspective was used to justify a genetic basis for the male dominance over the political and economic leadership, as well as the inherent female ability to be a caretaker and stay at home (Sork 1997).

Over human history, feminism obtained more visibility in society and collaborated to provide a new lens to research in a more ethical and accurate, scientific way (Rosser 1997). However, some feminists became strong oppositionists of evolutionary research, and some still are since the dialogue between feminism and evolutionary science demands the comprehension of evolutionary concepts, as well as a robust knowledge of the feminist cause (Vandermassen 2008). Although there are still many barriers that prevent the open dialogue on this topic, Darwinian Feminism emerges as a possible bridge.

Evolutionary psychology aims to comprehend how psychological mechanisms were selected and how they influence human behavior, while feminism advocates equal rights between the sexes (Wilson et al. 1997). Therefore, the Darwinian Feminism is the product of the last few decades

of the work of feminist researchers, who are also evolutionary biologists and evolutionary psychologists (Vandermassen 2008).

Despite the effort of researchers from the Darwinian Feminism perspective, evolutionary psychology is still targeted as sexist. This occurs when evolutionary analyses provide only biological explanations for oppressive behaviors seen nowadays, e.g., rape and male coercive sexual strategies (Wilson et al. 1997). The misunderstanding, however, lies in the necessity to acknowledge not only a holistic feminist point of view, but also how evolution and natural selection occur and its impacts on interpersonal relationships between men and women. From this point onward, it is possible to comprehend that explanations from an evolutionary perspective do not intend to justify oppressive male behaviors; rather, it aims to promote researches to improve understanding about the process involved in those mechanisms to possible future interventions.

For example, Eagly and Wood (1999) are evolutionary psychologists that proposed an explanation for the origin of sex difference in human behavior. To do so, they used the theory that different social roles between men and women would provide environmental pressures to select different psychological mechanisms between the sexes. Considering that research has shown that the human brain is highly sensitive to environmental change, once natural selection favored individuals with flexible responsiveness to extremely variable conditions (Smuts 1995), the human behavior can easily be modified in the short term if the environmental pressures change. Leadership ability, for example, taken as a masculine ability for centuries and even legitimized by science as an evolved mechanism for the male, could be observed in women that are put into high-hierarchy positions (e.g., Chief Executive Officer of a company).

Conclusion

In sum, based on social dominance and coercive strategies, men have been privileged within a gender-based hierarchical system entitled

Patriarchy. Although this social system has shown an evolutionary function for both men and women, the divergence of interests between the sexes has built an oppressive social structure for women.

Female resistance to male dominance created the Feminist Movement, in which plural perspectives were elaborated and had shown impacts on society as well as on the evolutionary research field. Nevertheless, the human species is highly responsive to environmental changes and, therefore, extremely capable of adapting to new social systems that do not represent an oppressive structure for either women or men.

University of Lethbridge, Lethbridge, AB,
Canada

Definition

Paul L. Vasey is a Professor and Board of Governors Research Chair at the University of Lethbridge in Lethbridge, Alberta, Canada. He conducts cross-cultural and cross-species research on the proximate and ultimate underpinnings of non-conceptive sex in humans and non-human animals.

Synonyms

Cross-cultural comparisons; evolutionary paradox of male same-sex sexual attraction; Cross-species comparisons; Evolutionary psychology research

Introduction

Early Life and Educational Background

Paul L. Vasey was born in Toronto, Canada, on January 30, 1966. Vasey was awarded his B.A. (Honors) from the University of Alberta in 1989. In 1991, he received his M.A. from Simon Fraser University. In 1997, he received his Ph.D. from the Université de Montréal. Dr. Vasey conducted postdoctoral research at the Université de Montréal, Concordia University, and York University.

Research Interests

Japanese Macaque Research

From 1995 to 2015, Paul L. Vasey conducted research on the development and evolution of same-sex sexual behavior among female Japanese macaques (*Macaca fuscata*). During this time, he observed captive and free-ranging Japanese macaque groups in Arashiyama (near Kyoto), Jigokudani (in the Japanese Alps near Nagano), and Minoo (near Osaka). This work has contributed to a greater understanding of the development and evolution of same-sex sexual behavior while challenging several assumptions common to the animal behavior literature.

Vasey and his research group demonstrated that same-sex sexual activity among female Japanese macaques does not serve a sociosexual function (e.g., aiding in alliance formation, communicating hierarchical position, or soothing conflict) (reviewed in Vasey 2006). Based on this evidence, Vasey proposed that it was possible for same-sex sexual behavior to exist as an evolutionary by-product, which is neither adaptive nor maladaptive for the species. This evidence-based claim challenged the predominant idea in the animal behavior literature that same-sex mounting is used to facilitate social goals. Further, he showed that the majority of female mounters stimulate their genitals, suggesting that this behavior is indeed sexual (reviewed in Vasey and VanderLaan 2012).

Vasey's group provided evidence countering the notion that females only engage in same-sex

behavior in the absence of sexually available males. They showed that female Japanese macaques actively reject soliciting males in favor of sexual consortships with females (Leca, Gunst, Huffman and Vasey 2015). Vasey also showed that females will, at times, engage in intersexual competition with males for female partners (Vasey 1998). Additionally, he and his research group found that juvenile females sexually debut earlier with females than with males (Leca, Gunst and Vasey 2015). They suggested that this developmental difference occurs because adult females solicit proceptive juvenile females for sex, whereas adult males act aggressively toward them.

Further, female mounting-posture patterns are flexible and arbitrary because they are unconstrained by penile-vaginal insertion (Leca et al. 2014). Female Japanese macaque same-sex mount postures vary between populations (Leca et al. 2014). This cross-population variation in an arbitrary behavioral expression suggests that, in this species, female-female mounting behavior is partially influenced by social processes.

Cross-cultural Research

In addition to his macaque research, Paul L. Vasey has carried out long-term research on the development and evolution of androphilia (i.e., sexual attraction and arousal to adult males) among human males. Vasey and his research group have studied this phenomenon in Independent Samoa, Canada, the Zapotec Istmo of Oaxaca (Mexico), and Japan. Because heritable traits that reduce reproduction are expected to become extinct, the persistence of male androphilia has been characterized as one of the major outstanding evolutionary paradoxes of evolutionary psychology. Vasey and his research group have made several important contributions toward resolving the paradox of male androphilia.

Male androphilia tends to manifest in either the masculine form (e.g., cisgender gay men) or the feminine form (e.g., gender nonbinary males). Both forms may be present within the same culture but one tends to predominate. Vasey and his research group have demonstrated that numerous developmental and psychobiological correlates

are common to masculine and feminine androphilic males alike. Namely, compared to gynephilic males (i.e., males who are attracted to adult females), both forms have more of older brothers, larger family sizes, more androphilic male relatives, similar population prevalence rates, little or no offspring production, increased gender nonconformity in childhood and adulthood, and elevated traits of childhood separation anxiety (reviewed in Vasey and VanderLaan 2014). As such, it is likely that the feminine and masculine forms are different behavioral expressions of the same underlying biological disposition.

In an award-winning paper, Vasey's research group found that conditions thought to typify the ancestral human sociocultural environment were more prevalent in cultures in which feminine androphilic males predominate compared to cultures in which masculine androphilic males predominate (VanderLaan et al. 2013). This suggests that the feminine form of male androphilia is evolutionarily ancestral to the masculine form. Consequently, the outcome of evolutionary processes may be obscured when using more derived forms of male androphilia (e.g., the masculine form), which may reflect historically recent cultural influences. As such, feminine androphilic males likely represent better models for understanding the evolution of male androphilia.

Vasey's group has repeatedly shown that feminine androphilic males in Samoa, known locally as *fa'afafine*, are more avuncular (uncle-like) than Samoan women and gynephilic men (reviewed in Vasey and VanderLaan 2014). Further, *fa'afafine* engage in avuncular behaviors in the absence of social pressure to do so. In childhood, *fa'afafine*'s altruistic tendencies appear to manifest as heightened anxiety related to concern about the well-being of kin (reviewed in VanderLaan et al. 2016).

Work by Vasey's group also indicates that *fa'afafine*'s avuncular tendencies could potentially increase their indirect fitness (reviewed in Vasey and VanderLaan 2014). Additionally, Vasey's group demonstrated that their avuncular cognition exhibits adaptive design features (e.g., *fa'afafine* are specifically interested in nieces/nephews and not kids generally; they are more

likely to invest in their sister's offspring than their brother's offspring) (reviewed in Vasey and VanderLaan 2014). This work furnishes support for the kin selection hypothesis, which states that genes for male androphilia could be maintained in a population if enhancing one's indirect fitness offset the cost of not reproducing directly. Theoretically speaking, androphilic males could increase their indirect fitness by investing in kin and, in doing so, facilitate the survival and reproduction of kin.

However, Vasey's research group has found virtually no support for the kin selection hypothesis in Canada or Japan, where the masculine form of male androphilia predominates (reviewed in Vasey and VanderLaan 2014). Consequently, they have proposed that a disposition toward investing in kin is contingent on feminine expression. Thus, gender expression may be relevant to the maintenance of genes underlying male androphilia via kin selection processes.

Vasey's group has also amassed some support for the Sexually Antagonistic Gene Hypothesis (SAGH). The SAGH posits that genes associated with the development of androphilia result in decreased reproductive output in male carriers, but the same genes result in increased fecundity in female carriers. A basic premise of this hypothesis is that androphilic male's maternal-line female relatives should produce more offspring than those of gynephilic males. Vasey's group repeatedly demonstrated that the mothers and maternal grandmothers of *fa'afafine* exhibit elevated reproductive outputs compared to those of gynephilic males (reviewed in Semenyna et al. 2017). However, to date, Vasey's group has failed to demonstrate elevated reproduction among *fa'afafine*'s maternal aunts. Because androphilic and gynephilic males share genes with their maternal aunts but not their aunt's reproductive partners, elevated reproduction by aunts would provide the clearest support for this hypothesis.

This body of work may be interpreted to suggest that male androphilia arose as an evolutionary by-product of sexually antagonistic selection for genes that promote elevated fecundity in females. The ancestral, feminine form of male androphilia tends to predominate in cultures with

maximally inclusive kinship systems and social tolerance of androphilic males (VanderLaan et al. 2013). These social conditions may have encouraged greater kin investment by androphilic males. Thus, feminine androphilic males may be particularly likely to behave in a manner that could facilitate greater offspring production by their female relatives. This, in turn, would have serendipitous effects on the sexually antagonistic genes in question even though androphilic male's heightened avuncularity was not originally selected for this purpose.

Androphilic male's elevated avuncularity might have resulted in greater offspring production by their kin. If heightened kin investment did, indeed, produce an indirect fitness advantage, kin selection processes may have acted to further refine androphilic male's avuncular cognitions to optimally facilitate reproduction among kin who share genes by virtue of common descent. This suggestion is consistent with the findings that *fa'afafine's* avuncular cognition exhibits adaptive design features (reviewed in Vasey and VanderLaan 2014).

Conclusion

Dr. Paul Vasey's cross-species and cross-cultural research has contributed to the field of evolutionary psychology by addressing the evolutionary puzzle of non-conceptive sexual behavior. Dr. Vasey and his research group have shown that social factors can influence the expression of same-sex sexual attraction. Additionally, he and his research group have made considerable strides toward understanding how male same-sex sexual attraction is maintained in the population despite lowering individuals' reproductive output.

Peer Competition and Cooperation

Ivan Dario Gonzalez-Cabrera
Konrad Lorenz Institute for Evolution and
Cognition Research, Klosterneuburg, Austria

Synonyms

[Competition](#); [Cooperation](#); [Intragroup competition](#); [Intragroup cooperation](#)

Definition

Peer competition is a form of social interaction in which at least two organisms of a peer group strive to obtain a limited resource or achieve a certain goal. Peer cooperation is the social interaction between at least two organisms of a peer group in which at least one of them acts in a way that fosters the benefit of other group members, regardless of whether those actions are beneficial or not to the actor herself.

Introduction

The study of peer competition and cooperation is essential for providing a theoretical account of human nature and its distinctive cognitive and motivational psychology. Research in these areas also has important practical implications. An accurate understanding of peer competition and cooperation is crucial, for instance, for understanding the factors that drive human conflict, as well as for overcoming the challenges that require collaborative effort, such as building and maintaining a large-scale irrigation system for agricultural production.

Peer competition and peer cooperation can be intuitively seen as opposing phenomena. However, depending on multiple factors, they might be complementary. In a population divided into groups, for instance, members of each group may cooperate with their peers in order to compete

with neighboring groups. Alternatively, they may compete with their peers as a means of choosing the best cooperative partners and demonstrate that they are reliable cooperative partners. For instance, if subjects can choose with whom they wish to interact, this may create competition to be more generous or loyal than others.

Drawing upon the developmental and comparative psychology literature, this article discusses the biological and cultural factors influencing the psychology of peer competition and peer cooperation in humans. Data from comparative psychology are useful to address questions about cognition from a broad evolutionary perspective. Developmental evidence, in turn, provides crucial information about how cognitive capacities emerge during the organism's life span, which will help to better illuminate how developmental trajectories are shaped by evolutionary processes. A special emphasis will be given to cooperative behavior, which, arguably, encompasses the most distinctive cognitive traits of the human species. The article ends by examining one of the most promising avenues of research on the psychology of peer cooperation: the *shared intentionality hypothesis*.

Evolutionary and Psychological Perspectives of Peer Competition and Cooperation

Peer competition and peer cooperation each possess a psychological and an evolutionary dimension. As such, research can focus on either the psychological mechanisms of competition and cooperation or the evolutionary explanations for them. For example, testosterone levels mediate competitive behavior when social challenges need to be confronted, and may also promote prosocial behaviors when this behavior enhances social status – e.g., when punishing norm violators brings reputational benefits to the punisher. The mechanisms involved in testosterone production are shaped by evolutionary forces that often have cascading effects on other traits. It has been argued, for example, that selection for increased social tolerance in the Middle Pleistocene led to a

decrease in testosterone levels (or perhaps reduced androgen receptor densities), which resulted in changes in human craniofacial morphology. The evolutionary trajectory of the hominin lineage seems to be characterized by both an overall decrease in aggressive behavior and an increase in social tolerance (Gonzalez-Cabrera 2017).

Much of the literature on the evolutionary dynamics of competition and cooperation focuses on formal mathematical models that apply insights from game theory. Models that focus exclusively on the ultimate explanation of cooperation (i.e., the reason why cooperation evolved), however, do not explain much about the psychological capacities or the specific neural systems that implement those cooperative behaviors. This is because cooperative behaviors could be implemented by different sets of psychological processes and neural structures that are functionally equivalent. As a result, a diverse range of mechanisms could evolve by natural selection to serve the same biological function. Many brain structures can serve the same purpose, for instance, in the same way that multiple morphological structures, such as wings in insects and birds, were selected for flying. Conversely, attention to the proximate mechanisms of cooperation (i.e., those psychological and biological substrates that explain how the organism reacts in the way that it does) helps to constrain evolutionary explanations, narrowing down the specific path by which cooperation could have emerged in a species. Thus, considerations about the proximate mechanisms of competition and cooperation are crucial for building more detailed models of the evolution of social behavior in humans and non-human animals.

For the most part, this article will set aside formal discussions in game theory and evolutionary game theory in order to focus on competition and cooperation primarily as psychological phenomena. This requires drawing a conceptual distinction between the evolutionary and the psychological variants of these phenomena. From a purely evolutionary point of view, competition and cooperation can be understood in terms of the *fitness consequences* that a certain behavior

has. Competitive behaviors are those that provide a fitness benefit for the actor and which are selected for because of their beneficial effect on the actor; cooperative behaviors, in contrast, are those that provide a benefit to other individuals and which are selected for because of their beneficial effect on those individuals who receive the fitness benefit. However, an organism need not have a mind for either competition or cooperation in the evolutionary sense. Viral and bacterial pathogens, for instance, cooperate in this sense when they cause human respiratory diseases. Psychological competition and cooperation, in contrast, are understood in terms of the *intention of the actor*. While competitive behaviors are those with which individuals intend to gain something (e.g., by establishing physical superiority over others), cooperative behaviors are those performed by individuals acting with the intention to benefit others, regardless of whether they intend to benefit themselves.

The rest of the article is organized into three sections. The first section outlines the conceptual framework of peer competition, its developmental trajectory, cultural differences, and the effect of both biological and cultural factors on those differences. The second section examines the psychological literature on peer cooperation. For theoretical purposes, the large body of empirical research on peer cooperation will be divided into two main lines of research: one focused on the mechanisms for generating the benefit of cooperation, and another focused on the mechanisms for distributing it. Generating and distributing the benefit are the two problems that individuals need to solve in order to achieve and maintain cooperation. Particular attention will be paid, to how the psychological mechanisms that deal with those problems emerge during human development and how they arose in evolutionary time. The third section focuses on the recent surge of psychological research on shared intentionality. The study of shared intentional psychology has provided a new and fruitful research program for understanding the distinctive nature of human cooperation. Competing accounts concerning the evolution and influence of shared intentionality on human cooperation will be analyzed.

Peer Competition

Understanding the phenomenon of peer competition not only requires conceptual clarity about what “competition” means but also some appreciation of the nature of peers and peer groups. Broadly construed, peers are those members of one’s social group with whom one shares certain social features such as age, interests, education, and social status. Overall, peers are psychologically relevant because they are likely to influence each other’s beliefs, values, and behavior. Depending on our explanatory interests, some features of social groups such as age and biological sex might be especially important in defining peer groups, while others such as spatial proximity might not. In many competitive sports, for instance, the age and biological sex of players are relevant to determining group membership, while their spatial distribution across the field is not. Careful attention to these defining features of peer groups is important because they make some patterns of social influence more salient than others and peer groups may display different forms of organization and social dynamics. For example, different forms of interaction can be observed among children of different ages, and further patterns of interpersonal relationships can be discovered when biological sex is taken into consideration.

Derivatively, peer competition can be roughly understood as the social interaction between at least two organisms within a peer group for a limited resource. Although, at a very general level, all species engage in biological competition to survive and reproduce, peer competition in humans is characterized by a set of distinctive psychological mechanisms. One salient difference is that competition in our species is significantly influenced by culture via implicit and explicit social norms. The effect of culture on competitive behavior is, of course, a function of different biological factors that can be shaped by evolutionary forces. For example, while some adaptations for peer competition emerge with age and enculturation, some others allegedly depend on biological sex. Understood as the systematic study of the biological basis of all social behavior, early

sociobiology tended to overemphasize the role of biological factors and the importance of biological evolution in shaping human social behavior. However, subsequent advances in evolutionary psychology have become more conscious of this limitation by paying more attention to the role of culture and evolution-like processes of cultural change. To the extent that distinctive forms of human peer competition are largely determined by cultural factors, the emergence of these special forms of competitive behavior deserves further discussion.

Developmental Trajectory of Peer Competition

While the relative impact of culture in human competition increases with age, adaptations for early peer competition seem to be strongly canalized in development: the emergence of those adaptations appears relatively impervious to variations in the environment or genotype of the organism. For example, human newborns have to compete for parental resources with both older and even yet-to-be-born siblings, because parents might continue to invest in their older children or invest in a new offspring as soon as the mother resumes ovulation. Thus, infants and toddlers need to appeal to others by engaging caregivers emotionally and, later in life, by monitoring their tastes and intentions using specialized cognitive mechanisms to secure adult attention (Hrdy 2009; Tomasello and Gonzalez-Cabrera 2017).

These adaptations for early competition are likely the result of concurrent processes of social selection in which conspecifics compete for access to resources other than mates. With the evolution of cooperative breeding in *Homo erectus* around 2–1.8 million years ago, hominin mothers could have babies at more closely spaced birth intervals than other apes due to the help received from others. Cooperative breeding is a social system in which offspring receive care not only from their parents but also from other group members, often called “alloparents.” Thus, in a cooperative breeding system, mothers had to divide their care and attention to offspring more

than other apes and to delegate responsibility for their offspring’s care to alloparents. Children would then have had to compete more actively for care and attention, and they would have had to learn to deal with different adults more flexibly.

During early (1–6 years of age) and middle childhood (6–12 years of age), children are still engaged in a process of competition with siblings and peers for the care and attention of adults. Children often obtain attention from adults by making themselves useful to them in everyday activities. This is especially clear in natural-fertility populations in which people make no conscious effort to control fertility and, therefore, population growth depends primarily on physiological and ecological factors affecting fecundity. Children who are situated in these populations help their parents and caregivers in various ways, such as harvesting, fishing, collecting shellfish, and foraging for fruit (for a review, see Kramer 2010). In doing so, they contribute significantly to their own consumption and the economic output of the group.

Around age 6, children increasingly display what is known as “interference competition.” Interference competition occurs when an individual’s actions prevent another individual from achieving a goal. This is a special form of competition since it requires physical interference – individuals may also compete with one another by capturing resources faster than their competitors without the need for physical interference. Peer interference competition is a highly debated topic in the literature, and this is due, in particular, to gender and cross-cultural differences in the way it is expressed. For example, it is commonly assumed that males who actively attempt to prevent others from achieving their goals may gain a reproductive advantage. In contrast, empirical evidence suggests that females engage in interference competition primarily when resources are scarce and that they avoid direct interference competition to reduce the probability of incurring physical harm through retaliation. The supposed biological rationale behind these differences, as one would expect from early sociobiological models of social behavior, is that females bear greater responsibility than males for their

offspring’s survival. Hence, they must avoid physical harm, including interference competition that might lead to retaliation.

This view is supported by some cross-cultural studies that indicate that female aggression is primarily directed toward other women and that physical aggression is typically used by a female when her own life or her children’s lives are at risk. Since elimination of direct competitors through coalitional support reduces the probability of harmful retaliation when the coalition outnumbered the victim, it is thought that social exclusion is a more effective strategy among females than males. Evidence from some Western samples seems to indicate that this strategy is indeed more common among women (Benenson et al. 2013). However, gender-based differences in interference competition can be alternatively explained as a response to male-dominated environments as research on gender inequality in the workplace in industrialized Western societies seems to indicate. Further cross-cultural data is therefore required to settle this debate.

As children become more enculturated, role models and social norms begin to influence their competitive behavior (see Fig. 1). While there are few differences in children’s competitive behavior during early childhood, children from different cultural backgrounds begin to differ in their competitive behavior by middle childhood. For example, equal sharing is common among peers during

early childhood, especially when children collaborate to obtain a particular resource. However, as will be discussed in the section below, developmental trajectories for costly sharing diverge across cultures around middle childhood, in line with differences in the sociocultural niches that children experience (Callaghan and Corbit 2018).

Cross-Cultural Differences in Peer Competition

In general, the emergence of prosocial tendencies seems stable across developmental niches, when prosocial behavior is relatively low cost. Nonetheless, cross-cultural differences become salient under costly conditions in situations involving both helping and sharing (Blake et al. 2016). While disadvantageous inequity aversion (avoidance of receiving less than a peer) emerges by middle childhood across all populations studied, advantageous inequity aversion (avoidance of receiving more than a peer) has been shown to emerge only in some of the populations studied and only later in development. Overall, these results suggest that cross-cultural variation in adult norms of resource distribution shapes the acquisition of fairness behavior during childhood.

Adults influence children’s sharing behavior, but the nature and extent of this influence varies across populations. This variation might be

Peer Competition and Cooperation, Fig. 1 Consequences of cultural factors on peer competition through four developmental stages before adulthood

explained by differences in children's imitation of adult behavior in different cultural settings. Children in collectivist societies exhibit higher levels of imitation than children in individualist societies for instrumental tasks such as the retrieval of a prize from a puzzle box or a necklace-making activity (Clegg and Legare 2016). Collectivist societies typically emphasize obedience and conformity, especially children's obedience to authority figures such as parents and elders, whereas individualist societies emphasize children's autonomy and independence. Thus, it is thought that children in collectivist societies obey authority figures more than children in individualist societies, which results in increased imitation.

The influence of adults and cultural variation on competitive behavior often reduces potential conflict as interference competition becomes more common among children and adolescents. Cultural norms about the distribution of resources, for instance, shape social structures by regulating dominance hierarchies among peers. Dominance can be roughly understood as differential access to resources, territory, and relative power over others. Beginning in early childhood, implicit dominance hierarchies are established based on individual differences in physical prowess and social skills. But individual differences in dominance do not seem to significantly influence children's survival, as much of the necessary care and attention is already provided by parents and other adult caregivers. The importance of both dominance hierarchies and local cultural norms for the individual's fitness comes later in life.

Norm-Driven Peer Competition

As children progress into middle childhood, dominance is progressively determined by achievements in diverse cultural domains unique to humans, such as intellectual, musical, artistic, or athletic performance. Competition intensifies in adolescence as individuals begin to compete for reproductively attractive mates, which makes them increasingly aware of their place within the hierarchy. Most social interactions in children are regulated by models provided by adults or

straightforward norms that decrease the cost of competition among the young, facilitating them to compete for social status. This is in stark contrast with chimpanzees who, along with the bonobo, are one of the closest living relatives of humans. Juvenile male chimpanzees do not form a dominance hierarchy with their peers (Sandel et al. 2017). One possible explanation for this is that male chimpanzees begin to establish rank by dominating adult females, but adolescent males are often not physically prepared to face female retaliatory behaviors. This is also likely the case in bonobo populations in which there is no exclusive male dominance.

Social norms can regulate peer competition in a way that suppresses dominance hierarchies to a significant degree. This is evident in hunter-gatherer societies, which are consistently characterized as egalitarian, in the sense that political leadership is weak and ranking and stratification among adult males is relatively absent. Egalitarian behavior is found in a wide range of ecological settings, indicating that this feature of their social organization is the deliberate result of the group members' actions (Boehm et al. 1993). This egalitarian social structure, in particular, is considered a consequence of reverse dominance hierarchies in which leaders are dominated by subordinates who disapprove of hierarchical behavior. In this way, aggressive and competitive tendencies among humans are reoriented through cultural processes in a more prosocial direction.

These reverse dominance hierarchies are typically encoded in social norms that work as leveling mechanisms that prevent inequalities of wealth, power, and prestige. Among the !Kung, for instance, hunting success is known to be quite variable, but successful hunters are denied the opportunity to use their skills to build wealth and prestige. Rather than technical limitations, it is the value system of noncompetitive, egalitarian hunter-gatherers that seems to limit the development of agriculture. In these societies, sharing is imposed, and the accumulation of personal possessions such as clothing, tools, weapons, or bead ornaments is sanctioned. Hence, these rules restrict both the progressive accumulation of

wealth and the necessary investments that make agriculture possible.

Cross-cultural studies of behavior in experimental economics reveal that models based on self-interest often fail at predicting competitive behavior in small-scale societies (Henrich et al. 2005). Experimental economics uses experimental methods to study theoretical predictions of economic behavior. Research in this branch of economics has used a wide range of experimental paradigms including ultimatum, public goods, and dictator games to show that cultural, group-level differences such as degree of market integration (i.e., participation in wage labor and market exchange) and the relative importance of cooperation (i.e., the degree to which economic life depends on cooperation with non-immediate kin) significantly explain the level of prosociality expressed in these experimental games.

This cooperative behavior covaries with the costly punishment of noncooperative norm violators or, in other words, with the willingness of group members to pay the costs of punishing violators of prosocial group norms. Both evolutionary models and experimental research suggest that costly punishment is what allows norms of fairness and other prosocial behaviors to remain stable against invading defectors who behave in a selfish or antisocial manner. Yet, costly punishment is also able to stabilize arbitrary or even maladaptive norms within the group. These norms can spread in a population because, as the experimental evidence shows, children are able to imitate, for instance, the costly punishment of both equal and unequal offers in economic games from adult models, and the rates of imitation increase with age (Salali et al. 2015). That is, even when adults use costly punishment against those who make fair offers in experimental games, children imitate this behavior as if they were enforcing an antisocial norm of unfair behavior.

The above results illustrate how social norms not only curb competition as seen in societies with dominance hierarchies but can regulate competition in ways that favor increasingly hierarchical societies as well. Hierarchical organization is common in pre-state tribes headed by chiefs or “big men.” Social organization in large-scale

societies is also characterized by top-down power structures. Differences in social organization are fostered by variation in certain kinds of cultural practices and institutions. Storytelling, for instance, may help to broadcast social norms that coordinate prosocial behavior and promote cooperation (Smith et al. 2017). The so-called big gods and organized religion, in contrast, may foster the rise of increasingly stratified societies. Big gods are morally concerned deities who judge people’s behavior and exert supernatural punishment over norm transgressors. These moralizing gods are thought to play an important role in the emergence of complex societies by fostering prosocial behaviors such as cooperation and self-sacrifice (Norenzayan 2013). However, although there is a correlation between big gods and the rise of politically complex societies, the rise of big gods seems to have only played a causal role in maintaining and promoting social inequality (Watts et al. 2016).

In hierarchical social landscapes, individuals will compete intensely to climb the social ladder, which is not the case in societies with flatter social structures. If the social structure is hierarchical, individuals will try to optimize their position in the hierarchy based on an initial set of biological and culturally inherited conditions (such as education or inherited wealth) via individual within-group competition. This generates distinctive selective regimes that act on human populations. Egalitarian societies may have favored traits such as cooperation and low fertility, while inequality could have increased selection for within-group competition for social status, high fertility, and other selfish behaviors. Thus, individuals in the highest social classes within stratified societies may invest in cultural institutions that favor their own social status.

This investment in cultural institutions creates conditions for cultural group selection. Models of cultural selection extend the Darwinian account of evolution by natural selection in order to explain cultural change. Cultural group selection, in particular, accounts for the evolution of cultural traits as a function of the competitive advantage that these traits confer to social groups. Most evolutionary models assume that group-beneficial traits

are evolutionarily unstable. They are thought to be unstable because selfish individuals who do not collaborate with the group-beneficial traits can thrive within the group. But social interactions can result in multiple stable equilibria. This is because many different forms of social organization can become stable within a group if they are sufficiently supported by social norms and if there is concurrent punishment against norm violators (Boyd and Richerson 1992). Religious beliefs about big gods, for instance, are stable within the group because they are coupled with severe social sanctions and the threat of divine punishment, both of which deter free riding. Under these conditions, the costs and benefits of a specific behavior are transformed by the rewards and punishments that are associated with those social norms. With groups enforcing a variety of social norms that regulate within-group competition, selection can act upon different kinds of social behavior as well as the social norms that make them internally stable within the group.

On this view, an explanation of why stratified societies evolved could implicate group-level Darwinian processes. In other words, these societies evolved as a result of variation in norms that regulate within-group competition, as well as the selective advantage that more stratified societies obtain as a result of between-group competition. Simulation modeling suggests that stratified societies are more able to survive resource shortages in variable environments by secluding mortality in the lower classes and thus keeping the population low relative to carrying capacity (Rogers et al. 2011). In both variable and constant environmental conditions, the demographic instability that is generated by unequal access to resources also results in intense migration. This migration, in turn, drives the spread of such societies and the social norms that favor unequal resource distribution, even when population size is relatively small.

Moreover, since stratified agriculturalist societies were able to grow bigger by producing more food and resources, they were also more motivated, arguably, to expand and conquer neighboring territories, creating a strong incentive to invest in organized warfare. Evidence for warfare among prehistoric hunter-gatherers exists, but this

evidence becomes clearer in the archaeological record during the beginning of the agricultural revolution around 10,000 years ago, when humans transitioned from hunting and gathering to farming.

To sum up this section, the developmental trajectory of human peer cooperation is characterized by the increasing importance of culture. As children become more enculturated, cross-cultural differences in competitive behavior become more salient. These cultural differences owe primarily to social norms that regulate peer competition within the group – either by diminishing hierarchical social organization or by supporting it. The evolutionary stability of these norms depends on costly punishment, which can be transmitted early in childhood via imitation of adult models. As will be discussed in the next sections, social norms do not only regulate peer competition but depend on distinctive forms of peer cooperation for their existence. In the human lineage, the psychological mechanisms of peer competition and cooperation are highly intertwined.

Peer Cooperation

Norm-driven forms of peer competition are closely connected to human cooperative skills since they require norm compliance. The fact that people routinely comply with norms is genuinely puzzling since individuals frequently have selfish evolutionary interests in violating them. Certainly, norms can be enforced by costly forms of punishment. However, costly punishment is paradoxical precisely because it is an extreme form of cooperation that requires the agent to refrain from incentives to avoid carrying out punishment.

Peer cooperation can be roughly understood as a type of social interaction in which at least one individual acts with the intention to foster the benefit of other group members, regardless of whether those actions benefit the actors themselves. When individuals cooperate without regard to their own self-interest, their behavior is considered a case of *psychological altruism*. The form of costly punishment discussed in the previous section, for instance, is often considered

psychologically altruistic. However, not all cooperative behavior is altruistic in this sense. Mutualistic cooperation can be motivated by prudential reasons: an individual can cooperate with another because of the foreseen immediate or delayed returns of their cooperative behavior.

Understanding how cooperation evolves is not only a central issue in evolutionary biology but also in the psychological sciences. Various accounts of those cognitive abilities that are thought to be unique to humans often link the evolution of those features to the evolutionary history of cooperation in our lineage. From collective hunting to cooperative breeding, cooperation is a defining feature of human social life. For example, collaborative hunting, as observed among hunter-gatherers, seems to require the mastery of a set of special cooperative skills that go beyond those we see in our closest evolutionary relatives, the chimpanzee and the bonobo. This is because collaborative hunting relies on cognitive capacities such as role and task division, joint plans, and shared commitment, which are, arguably, uniquely human. To distinguish this psychologically rich form of cooperation from its less sophisticated counterparts, it will hereon be referred to as “collaboration.”

The Two Problems of Peer Cooperation

Explanations of the evolution of cooperation have primarily focused on what is sometimes called “the problem of distributing the benefit of cooperation”— namely, how cooperation can be maintained in the face of free riders that gradually undermine cooperative enterprises. This problem arises because cooperation requires groups to distribute the benefit of these ventures in ways that incentivize individuals to cooperate over time. But, as a rule of thumb, individuals have a strong incentive to free ride – i.e., to obtain the benefits of cooperation without paying the costs of generating it. As a result, free riding individuals become more successful than cooperators who bear the cost of cooperative activities, causing cooperation to progressively decline in the population. However, explaining the evolution of cooperation

demands not only an explanation of how the benefit is distributed but also of how it is *generated*. Successful cooperation sometimes requires skills for communication, division of labor, or task commitment that explain how the benefit is generated in a cooperative interaction. This problem is called “the problem of generating the benefit of cooperation” (Calcott 2008).

These two problems can be illustrated by a two-person “stag hunt” game, which involves a situation of social coordination. In this game, two hunters (or players) must decide simultaneously whether to hunt for stag or hare. Each player can successfully hunt a hare alone, which makes hare hunting the safer option. Hunting a stag, in contrast, requires cooperation from both players. If the two hunters agree to cooperate, they can successfully catch a stag, which is the preferred and more valuable game. If both players succeed in hunting a stag, the game is shared equally, as described in the payoff matrix in Table 1. This matrix defines, then, a solution to the problem of distributing the benefit of cooperative hunting: equal sharing. However, choosing to hunt a stag is risky since the other player may choose not to cooperate. If that is the case, the hunter who decides to go after the stag ends up empty-handed since the successful hunting of a stag requires both players. Thus, in order to generate the benefit of cooperative hunting, the two players need to coordinate their choices and to trust each other in their commitment to hunting a stag.

This distinction is psychologically relevant since mechanisms dealing with these two problems might be supported by two distinct sets of psychological mechanisms that are dissociated in

Peer Competition and Cooperation, Table 1 Payoff matrix of a generic two-person stag hunt game, where $a > b \geq c > d$. The payoff defined in the top-right corner cell describes a situation in which Player 1 decides to hunt a stag and Player 2 decides to hunt a hare. In this scenario, Player 1 obtains a payoff of c , and Player 2 obtains a payoff of b

		Player 1	
		Stag	Hare
Player 2	Stag	a, a	c, b
	Hare	b, c	d, d

both development (ontogeny) and evolution (phylogeny) (for a review, see Warneken 2018). On this view, while the capacity to *generate* the benefit of cooperation has evolutionary roots that we share, for the most part, with other great apes, there is little evidence that our ape relatives possess similar skills for *distributing* this benefit. This set of skills, furthermore, has a distinctive developmental onset. While many key skills for generating benefit through cooperation arise early in human development, the mechanisms responsible for distributing it in ways that protect cooperation against defection are acquired later, for they strongly depend on children’s acquisition of local social norms. For example, while basic capacities for helping, costly sharing, and collaborating arise relatively early during the first 2 years of age, mechanisms that help to distribute the benefit of cooperative activities – such as partner choice, partner fidelity, inequity aversion, and reputation management – begin to emerge at 3 years of age or later during middle childhood (see Table 2).

The Ontogeny of the Mechanisms for Generating and Distributing the Benefit of Peer Cooperation

There is significant evidence for the partial disassociation in ontogeny of the psychological

Peer Competition and Cooperation, Table 2 Time of onset of children’s skills for generating and distributing the benefit (see Warneken 2018)

Time of onset	Skills for generating the benefit	Skills for distributing the benefit
18 months	– Helping	
18 months	– Costly sharing	
14–18 months	– Collaborating	
21 months		– Partner choice
3 years		– Disadvantageous inequity aversion
3.5 years		– Partner fidelity
5 years		– Reputation management
7–8 years		– Advantageous inequity aversion

mechanisms responsible for generating and distributing the benefit of cooperation. Young children are not only able to identify cooperative partners but also seem to prefer them over uncooperative ones, as measured by their reaching behavior and preferential looking. By 2 years of age, children already possess context-sensitive expectations about equal resource distribution. At this age, for instance, children expect an experimenter to give a reward to each of two individuals who have worked together to complete a task, but not when only one of them has done all the work. It seems, however, that children’s evaluations are only able to regulate their social interactions in the cooperative direction later on in development. For example, 17- and 22-month-olds tend to help both antisocial and prosocial adult partners despite their preference for prosocial individuals, and 3-year-olds share indiscriminately in experimental tasks involving distribution of resources.

The best example of the delayed emergence of mechanisms for distributing the benefit of cooperation is children’s development of inequity aversion. Although children seem to expect an equal distribution of resources at a very young age, aversion to unexpected unequal distributions emerges significantly later. In fact, the two forms of inequity aversion discussed in the section on [Cross-Cultural Differences in Peer Competition](#) follow different developmental trajectories. While disadvantageous inequity aversion develops around 4 years, advantageous inequity aversion begins to emerge at around 8 years of age (McAuliffe et al. 2013).

The Phylogeny of the Mechanisms for Generating and Distributing the Benefit of Peer Cooperation

While chimpanzees and bonobos have basic capacities for generating the benefit of cooperation (such as skills for helping, sharing, and cooperating in mutualistic ways), they lack the distinctive machinery for solving the problem of distributing the benefit of cooperation. First, when a human or conspecific fails to retrieve an object that is out of reach, chimpanzees can engage in

instrumental helping and even select the correct tool from a set of options. Second, although only bonobos seem to be able to engage in active forms of food sharing, chimpanzees are also capable of sharing food with conspecifics in a passive way. They give food to others, for instance, when the food is difficult to monopolize or when they experience harassment from a beggar. Third, several studies with both species of African apes, chimpanzees and bonobos, indicate that they can cooperate with other conspecifics in a mutualistic fashion. For example, some studies have shown that chimpanzees will wait for a partner in a cooperative task, when the partner is necessary for solving the task and, therefore, for obtaining the food reward. They even actively solicit help from them or help them (e.g., by opening the door of the enclosure), so they can cooperate in the task.

Perhaps the most salient, but controversial, examples of the phylogenetic disassociation of the mechanisms for distributing the benefit between humans and other apes come from studies on partner choice and inequity aversion. While human children prefer helpers over mean partners, great apes prefer dominant individuals as these social relationships determine access to mating opportunities, food, and other resources. Even bonobos prefer individuals that hinder others over those that help. Yet, some researchers have argued that primates possess a sense of fairness. Their reason for doing so is that primates react aversely to experimenters when they see a conspecific receive better food than themselves (Brosnan and de Waal 2003). However, evidence for a sense of fairness in nonhuman animals have been somewhat difficult to replicate under more controlled conditions (Sheskin et al. 2014), leaving the phenomenon open to alternative explanations. A different account of these aversive reactions, for instance, is that seeing another individual receive high-quality food generates the expectation in the subject of receiving the same type of food. In fact, subsequent experiments in chimpanzees suggest that these reactions are better characterized as frustration for not getting the expected food, rather than aversive reactions based on a sense of fairness or some sort of social comparison with what conspecific partners obtain.

To summarize this section, explanations of peer cooperation require an account of how the benefit of cooperative ventures is distributed among group members, so that free riding does not undermine cooperation over time. Moreover, it needs an explanation of how the benefit of cooperation is generated. Psychological evidence indicates that humans possess specialized mechanisms for addressing these two problems. While basic capacities for generating the benefit of cooperation through helping, sharing, and collaborating arise relatively early in development, mechanisms for resolving the problem of distributing the benefit of cooperation – such as partner choice, partner fidelity, inequity aversion, and reputation management – only begin to emerge later during middle childhood.

Peer Cooperation and Shared Intentionality

Even though great apes and humans seem to share many of the skills required for generating the benefit of cooperation, there are still important differences in how humans and other apes address this problem. A significant body of research in developmental and comparative psychology shows that human cooperation is characterized by a set of unique skills that fall under the umbrella concept of shared intentionality. Shared intentionality is the capacity to coordinate social interactions through the sharing of mental states such as goals and beliefs. In the stag hunt game discussed in the previous section, for instance, both players could solve the problem of generating the benefit of cooperation by sharing their intention to create a committed partnership to hunt a stag.

Cooperative skills for shared intentionality seem to be in conflict with the idea that the mechanisms dealing with the two problems of peer cooperation explained in the previous section can be easily dissociated in both ontogeny and phylogeny. Indeed, skills of shared intentionality begin to emerge early in the context of child-adult interactions, but they continue to develop well into adulthood in the context of peer interactions.

One notable example is collaborative hunting in hunter-gatherers, which relies on joint goals and plans, task and role division, and shared commitment that begin to emerge during childhood. Moreover, skills of shared intentionality seem unique within the ape lineage, for comparative research has systematically shown that nonhuman great apes, with whom we share a common ancestor around 7 mya, systematically fail tests of shared intentionality (Call 2009). Thus, these skills are hypothesized to be adaptations for generating the benefit of cooperation that emerged, due to selective pressures unique to the hominin lineage, from an ape-like common ancestor who lacked these capacities.

Shared intentionality explains many of the features that make human cooperation different from great ape cooperation (Tomasello and Carpenter 2007). The *shared intentionality hypothesis* states that the distinctive nature of human cooperation is due to behavioral differences produced by the presence of these abilities in the human lineage. Different social and cooperative skills that were likely present in our ape ancestors seem to have been transformed by shared intentionality (see Table 3). First, great apes understand what other individuals see, but they simply follow another’s gaze to see if they are looking at something interesting, e.g., a piece of food. If they see nothing rewarding or valuable to them, they quickly stop looking. Human children are also able to see what others see, but they are also capable of sharing the attentional state in a way that involves mutual awareness that the experience is shared, as well as a shared interest in the object or event. From a

very young age, for instance, children are able to gaze at adults, point to an object, and then return their gaze back to the person with whom they are interacting. Children tend to focus their attention on objects and events that others are attending to because they seem to find it intrinsically rewarding to share those experiences with others. This facilitates the cooperative exchange of information. For example, children tend to show adults objects that are interesting to them and, in turn, follow an adult’s gaze to experience what is interesting for them. Adults can similarly bring objects in their surroundings to an infant’s attention solely by using eye gaze. This creates a psychological common ground that enables both cooperative communication and collaborative activities with joint goals.

Second, nonhuman apes use gestures and signals only to get what they want from one another, while young children also use gestural communication for cooperative purposes. Nine-month-old human infants often direct other people’s attention to objects through gestures aimed to initiate joint attentional interactions. Twelve-month-old infants use pointing to share interest and attention with adults as well as to inform others of things they might not have seen or know when there is no benefit for themselves (Liszkowski et al. 2006).

Third, while nonhuman great apes regularly engage in group activities such as hunting, these activities do not seem to involve individuals cooperating through shared goals to which they are all both committed and mutually aware of one another’s commitment. Group hunting may be cooperative, but not necessarily “collaborative” in the psychological sense specified at the beginning of the previous section. Experimental evidence suggests that 18- and 24-month-old children understand group activities around shared goals as involving commitment from all the parties involved. At this age, infants actively encourage an unresponsive adult to rejoin a game by communicating with them in various ways. In contrast, in the same experimental situation, chimpanzees never try to reengage their partners but rather focus on solving the task by themselves (Warneken et al. 2006).

Peer Competition and Cooperation, Table 3 Basic social and cooperative skills in great apes that are transformed by human-shared intentionality (see Tomasello and Carpenter 2007)

Individualistic (great apes: chimpanzees and bonobos)	Collaborative (humans: 1-year-olds and infants)
– Gaze following	– Shared attention
– Social manipulation	– Cooperative communication
– Group activity	– Collaboration
– Social learning	– Instructed learning

Fourth, while social learning in nonhuman great apes is mostly opportunistic (since individuals gather information from others unilaterally, copying only the actions that are relevant to achieve the desired result), human infants focus on causally irrelevant actions that they think are intentionally demonstrated by an adult. In other words, children *imitate* adult models in the sense that they learn the detailed actions that others perform (in a seemingly intentional way) to generate a certain outcome. If an adult demonstrator knocks a music box three times before making it work, children will tend to do the same, even if they know the action is instrumentally irrelevant for making the box play the music. Opportunistic learning in nonhuman apes, in contrast, biases learning toward the *emulation* of causally relevant actions. Moreover, as in the music box example, adults often demonstrate to children what they should do, which makes learning a cooperative activity. When adults provide communicative cues that they are demonstrating something (e.g., by saying “This is the way we do it” or “This is the way it works”), 14-month-old infants copy the specific actions adults use much more often than when they do not explicitly instruct. If adults do not provide those cues, young children tend to only copy the result the adult achieved (Gergely and Csibra 2006). Remarkably, older children around the age of 2 not only learn imitatively, but they also seem to understand group activities with peers as normatively grounded (Rakoczy and Schmidt 2013). For example, when they learn from a model that a certain activity is performed in a certain way, children enforce the conventional rules of the activity when others violate them.

The Cooperative Origins of Shared Intentionality

Traditionally, the evolutionary origins of shared intentionality have been linked to obligate cooperative foraging, especially collaborative hunting. According to the *interdependence hypothesis*, our early ancestors had none of the adaptations for vertical climbing, forelimb suspension, and knuckle-walking. This precluded them from

seeking protection by quickly climbing to the trees or engaging in the type of hunting that we sometimes see in chimpanzees. Given the local predatory fauna, foraging alone (seeds, tubers, or meat) would have been a very dangerous task. Foraging and scavenging in a group for safety then became necessary during the Middle Pleistocene around 780 kya. In order to face those challenges, hominins required new adaptations for collaborative foraging. When nonhuman great apes face situations in which they need to decide whether to forage alone or cooperate with others to obtain a food reward, they lack the skills of coordination and communication that facilitate the reliable coordination of action, especially in the context of risky coordination problems such as the aforementioned stag hunt game (see Table 1). Thus, on this view, hominin ancestors likely lacked these adaptations until the selective pressures for obligate cooperative foraging came into effect, creating the conditions for the gradual evolution of more planned and coordinated foraging in the human lineage.

One trouble with this traditional evolutionary account of shared intentionality is that it does not explain why many of these capacities emerge so early in ontogeny. According to an alternative account, the *cooperative breeding hypothesis*, the key selective pressures responsible for the development of shared intentionality were linked to cooperative breeding, which likely evolved in *H. erectus* around 1.9 mya. This new rearing environment allowed humans to wean infants relatively early and, in doing so, reduce the time periods between pregnancies. This situation, as explained earlier in the section on the [Developmental Trajectory of Peer Competition](#), increased competition between siblings and peers who must monitor the whereabouts and intentions of adults in order to secure their care and attention (Hrdy 2009).

Consistent with this scenario, it has been argued that cooperative breeding could have selected for skills of shared attention in infants. Shared attention is not simply *parallel* attention. Operationally, an infant is sharing attention with her caregiver when (i) the focus of the infant and caregiver’s attention is directed to the same object,

(ii) the infant is able to track the caregiver's focus of attention, and (iii) the infant engages caregivers just for the sake of sharing with them that attentional state. Unlike human infants, nonhuman great apes do not seem able to share attention or other experiences with members of their own species. Chimpanzees and bonobos are indeed able to meet a version of condition (i) by focusing their attention in parallel to the same object. They can even meet similar requirements to those stated in condition (ii) by tracking other individuals' attentional states in competitive contexts such as food seeking. However, since these species seem to be motivated to follow another's individual gaze only for instrumental and competitive purposes, they crucially fail to satisfy condition (iii). Thus, it has been claimed that cooperative breeding favored the emergence of shared attention in our lineage because gestures and eye contact would be crucial to direct adults' attention to objects, to events, and to themselves, just for the sake of sharing with them pleasurable experiences that foster attachment and care.

Similarly, basic forms of cooperative communication could have also been a consequence of the early emergence of these shared intentional skills, for they could have emerged prelinguistically in the form of pointing and pantomiming. Nonhuman great apes sometimes point for humans in an imperative way, e.g., when they want an out-of-reach object. In contrast, human infants across different cultures point declaratively from around their first birthday. At that crucial developmental stage, human infants become highly motivated to share their interest in different objects and events by offering, showing, and pointing declaratively to them.

Overall, all these uniquely human infant behaviors would have evolved in the context of sibling and peer competition. For in the context of cooperative breeding, infants compete with each other to provide adults with positive affective feedback in order to secure care and attention. As a result, they could have used these skills to reward adults by sharing emotions, interest, and attention with them. Shared intentionality would have begun as an ontogenetic adaptation, i.e., as part of a sequence of specialized changes that

enabled infants to survive the cooperative breeding environment created by their parents.

However, as it will be explained in the next section, it is also likely that these early mechanisms of shared attention and basic cooperative communication coevolved as mechanisms to facilitate social learning (and perhaps even teaching), when adult activities required skills that demanded prolonged periods of preparation and maturation. This view explains the developmental trajectory of human skills for peer cooperation as the result of selective pressures for both cooperative breeding and cooperative foraging. These selective pressures are thought to collapse into each other during middle childhood – a developmental period in which children's dependence extends from their parents and other caregivers to cooperative peers. Thus, although some capacities for shared intentionality emerge early in ontogeny, others appear relatively late to support the generation of benefits via peer cooperation.

The Role of Ontogeny in the Evolution of Human Peer Cooperation

Accounts of the evolution of human cooperation have started to pay increasing attention to theoretical work in evolutionary developmental biology or “evo-devo” for short. Evo-devo focuses on how developmental processes evolve. A key tenet of this research program is that many evolutionary processes result from changes in developmental timing. Building upon this program, a recent hypothesis about the role of ontogeny in the evolution of human cooperation considers the trade-offs that emerge during the different stages of human development in order to provide an evolutionary account of the ontogeny of human cooperative capacities (Tomasello and Gonzalez-Cabrera 2017). An advantage of this account is that it not only explains the *evolutionary emergence* of those traits but also their *distinctive developmental trajectory*.

The evo-devo hypothesis of the evolution of human cooperation integrates insights from both the interdependence hypothesis and the cooperative breeding hypothesis. As in the cooperative

breeding hypothesis, it maintains that shared intentional capacities were initially geared to dyadic interactions between infants and caregivers. As children grow older, the model similarly assumes that most of the attention of adults is redirected toward younger individuals, which makes engaging caregivers progressively more complex. Yet, as time progresses, children also become more physically capable of helping and collaborating. Learning how to make themselves useful to adults in their everyday activities would have been a possible way to gain such care and attention. This is a plausible assumption given how significant children's contribution is for the overall economy of extant natural-fertility populations. By the age of 5, for instance, Hadza children provide 50% of their own caloric intake. Among subsistence agriculturalists, Maya boys provide 50% of what they consume, while girls produce the same percentage by the age of 6, once subsistence work includes food processing and household tasks (see Kramer 2010). As a result, basic abilities for shared intentionality and collaboration in early human children could have subsequently extended into adjacent developmental periods. This is an expected result of the selective advantages these skills provide in adulthood, at the cost of little or no disruption in the overall cognitive development of the organism. For example, basic skills for shared attention, cooperative communication, helping, and collaboration would have presumably conferred a great selective advantage to hunting partners in a context in which cooperative foraging was necessary for subsistence.

Moreover, building upon the interdependence hypothesis, the evo-devo model of human cooperation assumes that selective pressures stemming from increased interdependence created demands for more complex adaptations for coordination, communication, and shared commitment. These adaptations progressively moved "upstream" into childhood as a preparation for adult activities, in the sense that they began to emerge earlier in development. Most of this preparation would have occurred during middle childhood as it is in this developmental period that children need to learn how to make decisions with others with little

or no adult supervision. They are typically low-risk decisions such as choosing those activities that interest them and match their level of competence. But these decisions must be fair and impartial as participation is voluntary rather than forced. Children must interiorize the social benefits of sharing resources with others and learn how to be reliable cooperative partners. Thus, the transition to middle childhood opened a window of opportunity to learn key cooperative skills in low-risk contexts where failure to cooperate was not lethal.

A prime example of this is children's early skills for reputation management and normatively grounded cooperation. Reputation management is the capacity to adjust one's behavior in order to be judged by others in a more positive light. Normatively grounded cooperation refers to one's capacity to understand cooperative activities as involving commitment and to enforce those commitments. These skills could have initially emerged in adult individuals as adaptations for cooperative foraging. Later in evolution, they could have begun to emerge progressively earlier in development. This is because longer periods of maturation for these skills would have given individuals an evolutionary advantage when collaborative foraging was necessary for human subsistence. The primary selective pressures would have proceeded mainly upstream from adulthood and adolescence to childhood, enhancing their sensitivity to shared commitment and to the reputational effects of their own cooperative behavior. Arguably, this capacity did not evolve in the context of child-adult interactions since these relationships are hierarchically structured and, therefore, much more sensitive to other factors such as authority and fear of punishment. In contrast, starting from adolescence, individuals must collaborate with others for basic subsistence. Individuals with enough time to develop complex skills of shared intentionality, such as a capacity to form shared commitments and enforce them normatively, would gain a selective advantage. Moreover, since the networks of allies and friends that children build during this period will endure into adulthood, investing in a progressively earlier onset of complex skills for peer collaboration would have made a nontrivial difference in their fitness.

Consistent with this hypothesis, human child development is longer when compared with any other great ape. It also includes the appearance of middle childhood as a developmental period between infancy and puberty that is distinct from the juvenile stage of other great apes (Thompson and Nelson 2011). Traces of this process can be observed in the increasing awareness of the child about their own social reputation and the norms that regulate their social environment. Unlike nonhuman great apes, human children seem to be concerned about others' evaluations of their cooperative and prosocial tendencies because they appear to adjust their behavior based on their prediction of how others will assess this behavior. Experimental results indicate that 5-year-old human children, but not chimpanzees, share more and steal less when they are being watched by a peer than when they are alone (Engelmann et al. 2012). Between 6 and 7 years of age, children begin to enact fairness norms against selfish individuals and exhibit a deeper understanding of the normativity of social rules as arising from social agreement and commitment (McAuliffe et al. 2017).

To conclude this section, a number of alternative hypotheses have been advanced to explain the evolution of human cooperative skills of shared intentionality. The *interdependence hypothesis* argues that cooperative skills of shared intentionality evolved due to the selective pressures of cooperative foraging in the hominin lineage, while the *cooperative breeding hypothesis* explains its emergence as a result of the selective demands of cooperative breeding. An alternative approach, grounded in theoretical insights from evolutionary developmental biology, explains the emergence of cooperative abilities for shared intentionality as a consequence of adaptive changes in developmental timing stemming from both selective pressures. Further research on the evolutionary basis of human cooperation should focus on refining and testing these alternative hypotheses.

Conclusion

Human peer competition is determined by several biological factors (e.g., age, gender, and

physiology) and cultural factors (e.g., social norms). The degree to which each of these factors drives human social behavior, however, is a matter of dispute. Arguably, the influence of cultural factors increases with age as children become increasingly aware of the customs, norms, and values of their groups. Peer competition starts early in development as children must strive for adult attention due to human rearing environments of cooperative breeding that are unique among other great apes. As time progresses, competition becomes increasingly regulated by norms that influence social behavior, including sharing and distributing resources. These norms likely explain cultural differences in peer competition. Some evolutionary models might, as illustrated by some accounts of the correlation between big gods and the rise of politically complex societies, overstate the role of social norms in thwarting within-group peer competition. However, social norms can also intensify resource and status competition by stabilizing hierarchical social organization through different forms of normatively driven punishment.

Competition and cooperation among peers are, as we have seen, interconnected phenomena. When human peers compete over resources, they often do so by cooperating with others. Similarly, norm-driven forms of peer competition are closely connected to human cooperation because they require norm compliance. From a theoretical point of view, cooperating with peers involves psychological mechanisms for generating and distributing the benefit of cooperative ventures. Extensive empirical research suggests that several psychological mechanisms that allow humans to deal with the problem of generating the benefit are shared with other nonhuman great apes. Mechanisms for distributing the benefit in humans are, in contrast, more distinctive: specifically, they are closely connected with norms that regulate within-group competition. Somewhat more controversially, some evolutionary-minded psychologists have recently argued that the distinctive trajectory of these two classes of mechanisms is evident in ontogeny as well as phylogeny. Controversy about this distinction in phylogeny comes mainly from the literature on fairness and

inequity aversion in nonhuman animals. The fact that capacities for shared intentionality are uniquely human, and that some of them, at least, begin to emerge relatively late in development, also provides grounds for skepticism concerning the notion of a distinctive ontogenetic and phylogenetic trajectory.

Humans are characterized by psychological mechanisms of shared intentionality that have helped to coordinate increasingly complex cooperative activities in the hominin lineage. In this sense, shared intentionality can be understood as a uniquely human capacity for generating the benefit of cooperation. Shared intentionality transforms several social skills that humans share with great apes such as chimpanzees and bonobos. Three basic accounts of the evolution of shared intentionality have been proposed in the literature: *the interdependence hypothesis*, *the cooperative breeding hypothesis*, and *the evo-devo hypothesis*. The first account explains the evolution of cooperative skills of shared intentionality as result of selection for collaborative foraging in adults. The second argues that these skills evolved due to the selective demands of cooperative breeding. The third approach explains the emergence of these abilities through a composite explanation: selective pressures for cooperative breeding in humans, in addition to changes in developmental timing in adult skills for collaborative foraging that required longer periods of maturation, jointly explain the evolution of cooperative skills. Evidence for this hypothesis can be found in the distinctive developmental pattern of middle childhood in humans. Choosing between these competing hypotheses, however, requires further investigation.

Peer Effect

► Peer Pressure

Peer Feedback and Norms

Nathaniel Cooper
University of South Carolina – Beaufort,
Bluffton, SC, USA

Synonyms

Peer pressure

Definition

When members of one's social group respond positively and negatively to approved social behaviors and disapproved social behaviors, respectively.

Introduction

As children develop, their behavior becomes increasingly influenced by their peers. This is often due to the social acceptance and/or rejection that children receive from peers in response to particular behaviors – socially approved behaviors are met with social acceptance and positive feedback, while disapproved behaviors are met with social rejection and negative feedback. This peer feedback can also differentiate according to gender and age. The following entry reviews the literature on peer feedback and norms to display the possible age and gender differences regarding feedback within peer relationships. It will also discuss the impact that feedback can have on a child's social development.

Need to Belong Theory

Popular beliefs regarding human behavior have changed as new theorists have arisen and staked claims based on empirical evidence. Freud (1930) proposed that the two major driving forces behind humans' actions are sexuality and aggression. John Locke proposed that infants are born as "blank slates." Baumeister and Leary (1995) propose – with their *Need to Belong Theory* – that the actual driving force for humans is a biological need to establish and sustain interpersonal relationships. The interpersonal relationships that humans form have survival and reproductive benefits and are therefore believed to have developed as a result of evolutionary selection pressures.

Some of these evolutionary pressures are, metaphorically speaking, double-edged swords. For instance, researchers have examined how participants in need of social acceptance performed

certain tasks when offered incentives and when not (DeWall et al. 2008). Findings revealed that, when offered a social reward as an incentive, participants performed poorly on laboratory performance tasks and quickly provided excuses for their performance as a means of preventing or mitigating any peer rejection caused by their poor performance. When offered a monetary reward, the participants showed greater performance on the same task. The researchers concluded that, when there are no clear immediate benefits, humans would rather opt not to try than to experience social rejection due to personal failure.

Assimilation

Assimilation is the process of taking in and fully understanding information and/or ideas. Humans have a biological need to be assimilated into certain cliques/groups. As individuals find others who share many of the same attitudes and/or beliefs, this increases psychological comfort and subsequently the desire to be part of that group (Baumeister and Leary 1995). If this occurs at a young age, as individual ideas and concepts are being developed by individuals in the child's social environment, then peers can influence future decision-making as well as personality (Larsen and Buss 2010).

Gray and Rios (2012) conducted a study with students in a classroom setting where the students were primed for a need to assimilate or differentiate themselves from their peers. Focusing solely on the aspect of assimilation, students were asked to rate academic tasks based on how well the task would allow them to fit in with their peers. Therefore, students rated tasks higher based on how well the task would allow them to fit in with their peers. When participants were primed, the participants with the thought processes of wanting to assimilate into the group, performance on the highly rated tasks (i.e., tasks that allow individuals to assimilate into their peer group) dramatically increased. Primed participants were willing to go the extra mile, so to speak, in order to perform the task well, so that they would align with their

primed condition. This shows that individuals may choose to act in the interests of becoming one with the group.

This phenomenon is not novel, as it has been the theme of many films and television shows throughout the twentieth century. The movie *The Sandlot* (1993) – which is about the social relationships of a group of school-aged children in the 1960s – provides a depiction of assimilation and the positive effects that are a product of assimilation. *The Sandlot* (1993) begins when Scottie Smalls moves to a new neighborhood where he does not know any of his peers. He eventually meets the neighborhood boys and assimilates into their group while adopting their social and cultural practices (e.g., sleepovers, playing baseball, going to the local public pool, etc.). As his social acceptance grows, Scottie's self-esteem increases.

Breaking down the film in a more scientific approach, what we see in *The Sandlot* (1993) is that, young boys develop social relationships with individuals around the same age, same gender, and similar interests.

Failure to assimilate into a group, or society as a whole, can have adverse effects as well. Studies have found links between failure to socially assimilate and suicide (Baumeister and Leary 1995). Suicide has also been found to be prevalent for those who experience high rejection rates from groups they wish to join. This is one of the negative consequences of the process known as differentiation.

Differentiation

Differentiation is the process of creating distinctions between two objects. This can be both a beneficial and harmful concept. In the case of social relationships, differentiation refers to identifying oneself as separate – or excluded – from a particular social group. Differentiation can be harmful to individuals as it may lead them toward negative or depressive feelings (Stone et al. 2016). However, peers may pressure different peers to engage in harmful behaviors as a means of conforming to the group. For instance,

misconduct and antisocial activities are significantly correlated with peer pressure in adolescents (Gavazzi et al. 1993).

Differentiation, however, can also possess beneficial aspects. It can help individuals narrow down options for potential friends and allies, which can help them choose the social group (s) with which they wish to spend their time. Gavazzi et al. (1993) also found that high levels of peer support were associated with lower degrees of psychopathological symptoms and a greater degree of social competence.

A strong example of differentiation occurs in the novel *The Giver* (Lowry 1993). The main character Jonah is given the highest honor in the Utopian community in which he resides. He is chosen as the receiver of memories, which effectively and immediately sets him apart from everyone else in his community. As Jonah begins to receive memories and experience things that no one else in his community has been able to experience, the gap between himself and the rest of the community widens. Jonah begins to feel like an outsider because his peers share a much different viewpoint than he had come to know and understand. While this example starts off as an image of harmful differentiation, it reverses and becomes more of a beneficial tool as Jonah develops a unique mind and rejects his peers' black and white view of the world around them.

Positive Feedback

When individuals engage in a particular social behavior in the presence of their peers, the behavior is often met with a response from these peers. This response – which can be positive or negative – is referred to as *feedback* because individuals often utilize their peers' responses as a means of understanding which social behaviors are acceptable and which are unacceptable within their social group. Positive feedback refers to the approval and acceptance of a particular social behavior, which often comes in the form of some sort of reward (Salmivalli 2010). This reward may not always be a physical object – it may be

something as simple as smiling, laughter, encouraging statements (e.g., saying “good job!”) and positive physical contact from peers. Positive feedback operates as positive reinforcement – an individual engages in a particular behavior, his/her peers like the behavior so they subsequently reinforce that behavior by smiling and reacting happily and kindly toward the individual, which then encourages the individual to engage in that behavior again in the future.

However, positive feedback can have negative implications as well. Individuals may feel compelled to engage in negative, harmful, and even illegal behaviors because they are met with positive peer feedback. For instance, in one study, approximately 67% of participants aided and abetted fellow group members in lying, cheating, and stealing. This occurred even when the participants did not know the other individuals in their group (Geis and Moon 1981).

In addition, some individuals may find positive feedback through elevated social status among peers. For example, Salmivalli (2010) researched the structure of bullying in order to identify a way to weaken and eradicate such behavior. Her research concluded that most bullies committed aggressive acts as a means to establish dominance over their peers. This would give them the perception of being “cool” during certain times of the year. While the victim receives no positive feedback, the bully receives a lot of positive feedback via feeling powerful over his/her peers, which can reinforce the bullying behavior and cause it to continue or increase in frequency and severity (Salmivalli 2010).

Social popularity – a concept that is often associated with high levels of positive peer feedback – is also related to aggression and depression. Troop-Gordon and Ranney (2014) found that popular males tend to have a more aggressive demeanor to them, which is likely due to how males work their way up the social ladder, sometimes using aggression to assert. On the other hand, popular females are more affected by depressive symptoms (Troop-Gordon and Ranney 2014). This is likely due to females’ verbal aggression toward each other in order to climb their own social ladder (Geher 2014).

Negative Feedback

Although positive feedback can be utilized to reinforce negative behaviors within a social group, it must not be confused with negative feedback – which is the mechanism by which individuals illustrate which behaviors are disapproved within a social group. Negative feedback can come in the form of disapproving responses or social rejection. Stone et al. (2016) researched how rejection from peers influences depressive symptoms. In their study, they examined children previously diagnosed with major depressive disorder (MDD). A majority of these children were female. Researchers looked at pupil dilation and the retention of that dilation as a measure of how feedback affects and sticks with these young children. The researchers concluded that the effects of negative feedback and peer rejection were more pronounced in children with depressive symptoms. Specifically, pupil dilation lasted significantly longer than individuals without MDD. Furthermore, while positive feedback also had an effect on pupil dilation, the pupil returned to normal size at a much faster rate than those exposed to negative feedback.

There are two forms of negative feedback – representative negative feedback and non-representative negative feedback (Jansen et al. 2014). Representative negative feedback follows an incorrect decision, while nonrepresentative negative feedback follows a correct decision. Jansen et al. (2014) investigated children’s potential reactions to nonrepresentative negative feedback. Their findings revealed that children were more likely to change their answers to questions after receiving nonrepresentative negative feedback. This has been interpreted as a lack of understanding and differentiation of the two forms of negative feedback among children aged 6–12 years-old.

Conclusion

Human behavior and personality can be influenced by his/her peers in a variety of ways. When entering a peer group, the processes of

assimilation and differentiation often occur, which leads to acceptance or rejection from the peer group. As the research shows, assimilation tends to have positive effects for individuals, while differentiation tends to have negative effects (although differentiation can produce some positive effects as well). The processes of assimilation and differentiation occur via the mechanisms of positive and negative feedback from peers. While positive feedback often leads to social acceptance, it can also lead to some negative behaviors such as aggression, dominance, and bullying. Negative feedback, such as peer rejection, often leads to negative feelings and can even lead to depressive symptoms. Ultimately, the process of assimilation leads to positive and negative feedback (and sometimes differentiation), which can be a tumultuous time for individuals – especially children and adolescents who are beginning to develop their peer group and their sense of social belonging for the first time.

Definition

A group of people of approximately the same age who have similar interests, background, or social status. The members of this group are likely to influence an individual's beliefs and behaviors.

Introduction

For our ancestors, being a part of a group would have been critical for survival. Group membership would have offered benefits such as increased protection from predators, hostile out-group members, and challenging environmental conditions. Benefits such as these would be essential for reproductive fitness. As such, it is likely that the tendency to cohabitate, work, and play together in a group was favored by natural selection (Van Vugt and Schaller 2008).

In childhood, peer groups consist of individuals who spend time and interact with each other. In adolescence, peer groups are based increasingly around the reputation of its members. Therefore, peer groups play a particularly important role in socialization. Further, peer groups may not only provide a positive context for children and youth to be a part of beneficial relationships but can also have a large influence on the behaviors, beliefs, and attitudes of the individual members of the group. It is therefore important to consider that while there are often many benefits to being a part of such groups, it is also possible that aspects of these groups present certain risks to children and youth. The rest of this chapter will examine peer groups across the lifespan through an evolutionary lens by considering gender differences and potential costs and benefits of memberships in such groups.

Stratification of Peer Groups

The transition from childhood to adolescence marks a period of rapid stratification of individuals into peer group structures as adolescents move from elementary school to middle and high school. This period is characterized by increased levels of autonomy as peer relationships begin to supersede familial relationships. Further, during this period, adolescents experience new levels of reduced supervision (Volk et al. 2016). From a psychoanalytic perspective, this progression facilitates the process of *individuation*, which may be described as the manner in which adolescents restructure relationships with

parents and caregivers to accommodate new and different kinds of relationships with one's peers. This novel degree of independence from one's parents sparks feelings of vulnerability and anxiety in adolescents which, in turn, they attempt to quell through supportive and intimate relationships with their peers. Similarly, from a cognitive-developmental perspective, these new peer relationships are qualitatively different from previous relationships with adults, particularly in regard to the imbalance of power. The horizontal nature of friendships allows adolescents to explore opposing ideas and multiple perspectives, thus facilitating an advanced understanding of other persons as having independent thoughts and emotions.

During adolescence, the unified peer structure of childhood (i.e., elementary school) gives way to increasingly differentiated and stratified groups (i.e., middle and high school; Volk et al. 2016). General peer group structure changes to include various subcategories as individual's transition from childhood to adolescence. The broader level of peer group stratification is referred to as *crowds*, which describes large groups of individuals grouped together by common stereotypes or reputations who may, or may not, spend time together. Crowd membership is entirely dependent on assessment and consensus from one's peers (Rubin et al. 1998). Sussman et al. (2007) identified five major classes of crowds that are observable across many schools: (1) elites, the crowd with the highest social status; (2) athletes, the students who are known for their involvement in school sports and teams; (3) academics, the students who are both academically talented and socially accepted; (4) deviants, the students who are alienated from the larger student culture and are often involved in risky behaviors; and (5) others – students who, by in large, go unnoticed by most students. Stigmas and stereotypes associated with such crowds influence individual behavior and may constrain adolescents into relationship patterns and interests that are consistent with the crowd's reputation – for example, dating and sexual behavior. *Cliques* form within crowds, rather than across crowds. A clique is typically defined as 3–9 same-sex

adolescents, generally of the same race, that are linked together by friendship. Cliques are entirely voluntary and exist outside of the confounds of extraneous variables that may be imposed on adolescents by circumstance or by adults (Rubin et al. 1998). From an adaptive perspective, belonging to a group would have provided protection and safety from potentially threatening animals, persons, or other groups in the ancestral environment (Van Vugt and Schaller 2008).

Peer Groups as an Adaptation

Adolescence also marks a period of increased concern about one's reputation and acceptance from peers. These concerns are amplified by the increased stratification of peer groups and the resulting increased competition for social power and status (Juvonen and Graham 2014). From an evolutionary perspective, the benefits of group membership would not have been equally distributed among all members. Therefore, qualities that aided individuals in maximizing the social resources that were available to them through successful management of group dynamics would have been favored by natural selection (Van Vugt and Schaller 2008). As a result, adolescents may be compelled to use strategic tactics, some prosocial and others coercive, to obtain these limited social resources (Volk et al. 2016; Hawley 2003).

Social Dominance

Indeed, achieving high social status or dominance within one's peer group grants an adolescent access to adaptive advantages such as higher-quality mates and reputational benefits (e.g., Flinn and Ward 2005). Resource Control Theory predicts that children and adolescents use different strategies, consisting of different combinations of prosocial and antisocial behaviors, to attain social resources (Hawley et al. 2007). As such, popularity and being well-liked must be approached as two separate constructs. Being popular is associated with increased relational aggression, whereas being liked by one's peers is associated with decreased relational and overt

aggression in middle schoolers (see Hawley et al. 2007 for review). Similarly, children who have moderate levels of aggression, and who use that aggression instrumentally to achieve their goals, are perceived as more popular than children who are lower in aggression or children who use their aggression more recklessly (Hawley 2003).

While these adolescents may be regarded as popular and powerful within their peer network, they may not be guaranteed the benefits of altruism or affection from peers, especially if those peers do not readily accept this type of behavior. However, qualities such as forcefulness, assertiveness, strength, and Machiavellianism may be attributed to strong leadership skills by the group, thus granting individuals with these qualities enhanced social power and dominance. As such, high status, leadership, and aggression are often co-observed among adolescents (Hawley 2003). Both boys and girls compete for dominance in their peer groups, and the tactics used to attain such dominance reflect the differential reproductive pressures between the sexes.

Sex Differences in Peer Groups

Basic evolutionary theory predicts that reproductive pressures, such as the ones discussed below, will exert themselves differently between males and females. Furthermore, the social styles of boys and girls, influenced by everything from hormonal exposure in utero to culturally constructed gender role schemas, contribute to greater segregation.

Male Peer Groups

The structure of male peer groups evolved under selective pressures that made control over one's local environment (and the resources in it), control over mating opportunities, and influence within one's peer group adaptive. As such, boys will often organize into large male coalitions with dominance hierarchies (Geary 2010). From a sociocultural perspective, the emphasis in boys' culture on independence, autonomy, self-assertion, and competitiveness may exacerbate this tendency for boys to organize themselves

into large, loose-knit peer groups (Benenson et al. 2001). From an adaptive perspective, by developing coalitions among each other that emphasize status and dominance, boys may be more apt to compete against other groups of boys and protect their resources and kin (Geary 1998).

Within these loose-knit male peer groups, one-on-one and group-level competitive play among boys is ubiquitous across cultures and time periods. However, the degree to which play fighting is rough appears to depend on the degree to which male-on-male aggression is common within a particular cultural or historical context. For example, among the Yanomamö of South America, inter-group aggression is frequent in adulthood. Young Yanomamö boys are often given toys such as clubs, bows, and arrows, and play fighting often involves causing physical pain and harm to another. Furthermore, social norms dictate that pain not be expressed. As such, this culture emphasizes developing toughness, aggressiveness, and endurance and de-emphasizes sensitivity, thus preparing young boys for the life-or-death male-male conflict that they will encounter as adults (Geary 1998).

In the ancestral environment, men competed for social resources and capital within their groups, sometimes with deadly consequences (Geary 2010). To a lesser extent, this is still true of contemporary times. For example, according to Geary (2010), there is no significant difference between the motivations of a pastoral raider stealing another tribe's cattle or a white-collar criminal on Wall Street, as both examples reflect the desires of men to control resources relative to other men or groups of men. In these examples, men are not competing against one another simply for the purpose of amassing resources; rather, they are interested in attaining status in the dominance hierarchy and usurping the next person up in the ranks. This drive to attain resources makes male coalition forming adaptive – that is, forming coalitions would have provided benefits such as ability to control more territory, access to higher-quality mates, providing for family and kin through large-scale hunting efforts, and increased protection from other male coalitions. Furthermore, in the ancestral environment, the

dominance hierarchy would have facilitated coordinated group action, and the lack of emotional closeness would have facilitated building a larger coalition (discussed further in the next section; Geary 2010).

Female Peer Groups

Unlike boys and men, girls and women tend to organize into peer groups that consist of dyads or small groups of individuals who are of similar social status and are characterized by intimacy, personal disclosure, and support. Women tend to invest more heavily in the quality of their relationships rather than the quantity of relationships they maintain. For women, these peer group structures are also adaptive, as there are significant and immediate benefits in having a network of supportive friendships. In the ancestral environment, a female who maintained close friendships with other females would have increased her genetic fitness by attaining kin altruism and alloparenting of her own offspring from her female allies. Reciprocity (i.e., mutually beneficial exchanges), therefore, is an important characteristic of enduring female friendships. As such, women likely evolved psychological monitoring mechanisms that attune them to cues of nonreciprocal relationships and limit tolerance of such relationships (Geary 2010).

Therefore, while the intimate nature of female friendships is certainly beneficial, these same qualities may contribute to the swift undoing of female friendships. In the animal kingdom, research conducted by de Waal (1989) has demonstrated that female chimpanzees reconcile disagreements among themselves at a lower rate than their male counterparts. Similarly, research by Benenson and Christakos (2003) found that females, as compared to males, reported more fragility in their closest same-sex friendships. Further, females reported that their friendships lasted for shorter periods than males and were characterized by greater feelings of unease about the potential ending of their friendship. Moreover, while boys and men are more likely to engage in overt and physical aggression, it is well-established that girls and women are more likely to engage in relational or indirect aggression.

As such, the same personal disclosures that once formed the foundation for intimacy in a female friendship may leave an individual vulnerable to victimization in the event that the friendship dissolves (Geary 2010).

Potential Outcomes of Peer Group Membership

Well-Being and Health

Peer group involvement is associated with benefits to physical health, social development, and psychological well-being throughout the lifespan. As predicted by Abraham Maslow's hierarchy of needs, the inherent human need to belong is only superseded by other necessities such as food, water, and safety. Contemporary research has since highlighted the importance of belonging to a group, especially in adolescence. For example, Parker and Asher (1993) suggested that friendships within peer groups may fulfill specific needs for intimacy, social support, and instrumental aid. Furthermore, the intimate and accepting context of friendship may grant children and adolescents the significant benefit of a secure relationship in which they feel comfortable exploring different behaviors and attitudes (Parker and Asher 1993). Relationship strength in adolescence also predicts increases in self-worth and decreases in depressive symptoms in early adulthood (Narr et al. 2017). As such, it's not surprising that adolescents who report positive relationships within their peer groups often also report a strong sense of well-being.

Peer relationships also play a central role in the adolescent support system, offering youth encouragement to withstand emotionally challenging circumstances. In fact, research indicates that peer relationships may mitigate the harmful effects of environmental stress on adolescent mental health (Stanton-Salazar and Spina 2005). Moreover, the benefits of peer affiliation in adolescence include positive outcomes for future relationships. In this way, peer group membership and the relationships fostered within them provide individuals an important context for learning about the requirements of mature, respectful

interpersonal relationships (Stanton-Salazar and Spina 2005).

Into adulthood, peer groups continue to offer learning opportunities and social support networks. Peer group affiliation offers individuals the opportunity to observe and mimic the various coping strategies that others implement, therefore allowing the observer to evaluate the efficacy of such strategies and utilize them to cope with similar problems (Palmonari et al. 1991). In addition to offering social learning opportunities, peer groups fulfill important social support roles. This is particularly true following widowhood or divorce, where close peers take over the important functions that were previously provided by partners. Research suggests that after a spouse, older adults rank close friends as their most important source of support, ahead of adult children and other familial relations. The importance of peer relationships in filling that role may be attributed to secure attachment based on shared experience, reciprocity, and equality (Matt and Dean 1993).

Across the lifespan, peer group affiliation offers benefits to an individual's overall physical health as well as their emotional and psychological well-being. For example, greater social support and integration is associated with a decreased risk of morbidity and mortality. Specifically, research suggests that men who were more socially integrated with peers during childhood and adolescence reported lower blood pressure and body mass index 20 years later, both indicators of overall physical health (Cundiff and Matthews 2018). The benefits extend to women as well, with higher peer participation and encouragement being significantly related to a higher level of physical activity (Verloigne et al. 2016). These findings emphasize that the benefits belonging to peer group are not only social in nature but can extend to physical health benefits as well.

For some adolescents, peer groups may be a source of social stress. In particular, stress associated with peer groups is related to compromised emotional well-being, especially among young women. Furthermore, social stress appears to be strongly associated with lower self-esteem and higher depression for females but not for males,

while having social support through a peer group seems to have a stronger impact on males compared to females (Moran and Eckenrode 1991). Conversely, having strong social support fostered from a peer group was found to be associated with higher self-esteem and lower levels of depression more predominantly in males (Moran and Eckenrode 1991). It would therefore appear that the salience of the peer group context differs between the genders.

Academic Performance

Peer groups also have an important influence on youth achievement, beliefs, and behaviors in school contexts. As an inherently social space, the way that individuals engage with the school context is influenced by the attitudes of their peer group. For example, Ryan (2000) found that students with high-achieving friends have greater academic achievement over time as compared to students with lower-achieving friends. Similarly, this research also suggests that by associating with friends who have positive attitudes toward school, youth may enhance their own satisfaction with school, highlighting the influential role peers may be playing in adolescent academic achievement (Ryan 2000). Furthermore, associating with highly motivated peers may act as a protective factor during adolescence, a developmental stage typically characterized by heightened exposure to risk-taking behaviors.

Risk-Taking

The influence of peers has been found to play a large role in adolescents choosing to engage in risky behavior, as research demonstrates that when individuals are in peer groups, they tend to not consider the costs of risky behavior and, instead, focus on the benefits (Gardner and Steinberg 2005). This is evident in research by Gardner and Steinberg (2005), which found that adolescents were more likely to make riskier decisions when they were in peer groups compared to when they were alone. Further, this research found that the effect of peer groups to increase engagement in risky decision-making and behavior was stronger with adolescents than with adults. This emphasizes the influential role peer groups can

play, particularly during this stage of development. Considering these findings, adolescents within these types of peer groups may be more likely to engage in antisocial behavior, specifically bullying, as a means to attain resources such as increased social status.

Bullying and Victimization

The peer group may be an arena for antisocial or aggressive behavior. Aggressive behavior such as bullying may be considered a cost or benefit within a peer group, depending upon the role of the individual in the group (i.e., a bully versus a victim). From an adaptive perspective, bullying within a peer group may be a tool to attain resources such as higher social status within the group (e.g., Volk et al. 2014) and may therefore be considered as a benefit to the perpetrator. However, the overall cost may be that certain individuals in the peer group may be harmed (i.e., physically, emotionally). It is therefore important to take into account that membership of a peer group may produce benefits (e.g., may be a protective factor), but may also come with increased costs, particularly during adolescence. This may be particularly true if the individuals with the most status within the group are choosing to engage in antisocial behavior as a way of exerting control and attaining dominance over other members. Connected to this, reputation has been the most discussed benefit of engaging in bullying as it can be a means for both individual and group participation in dominance hierarchies (e.g., Volk et al. 2014; Salmivalli 2010). It may be a means to support in-group solidarity, as individuals have reported joining in with bullying as they did not want to be left out or as a way to emphasize their loyalty to the initial bully (e.g., Garandeau and Cillessen 2006). At the group level, this may also be another way to distinguish in-group versus out-group competition, as individuals who are members of particular groups may be encouraged to take part in bullying behavior to harm other groups. Further, bystanders to bullying behavior may choose to join in with bullying behavior as a way to try to attain membership into a more powerful (i.e., high social status) group (Salmivalli 2010).

Conclusion: Implications of Evolutionary Research on Peer Groups

Similarly, Spadafora et al. (2018) found that witnesses to bullying situations will choose to ignore the negative behavior when they perceive possible personal costs to them (i.e., loss of social status) and only consider intervening if there were direct benefits (i.e., it was a close friend being bullied or there was a potential for increased social status or to gain a friend). This research suggested that individuals within a peer group may make decisions, from an adaptive perspective, by considering personal costs and benefits to themselves. Furthermore, this research emphasizes the high value placed on social status by many adolescents who are involved in such groups. As such, future research should endeavor to use the adaptive perspective to achieve a better understanding of the social dynamics at play in peer groups and to use this information to create useful and effective interventions.

While peer groups can contribute to antisocial group behavior (such as bullying), they can also be instrumental in the success of anti-bullying intervention as seen through peer-based intervention programs such as KiVa (Salmivalli et al. 2012). Therefore, it may be important to further evaluate interventions that utilize both peers and the adaptive perspective such as the “Meaningful Roles” intervention as described by Ellis et al. (2016). This intervention focuses on offering alternative activities that can enhance an individual’s status, especially at the secondary school level as this is the time that social status seems to be most salient.

Peer Norm

► Peer Pressure

Peer Pressure

Bin-Bin Chen
Fudan University, Shanghai, China

Synonyms

Conformity; Peer effect; Peer norm

Definition

Peer pressure is the influence on people by peer-defined norms on how to behave, think, and feel.

Introduction

Living in social groups may enhance an individual's fitness. Throughout evolutionary history, humans have tended to live in large complex groups, and one of the reasons we evolved large brains was because having a large brain facilitates

interaction with a lot of people and the establishment and maintenance of a wide social network (Dunbar 2010). Because of the importance of group life humans are susceptible to peer pressure, in particular we are more susceptible to peer pressure than our closest living relatives, chimpanzees (Nettle et al. 2013).

Peer Pressure and Child Development

Peer pressure becomes apparent in early childhood, when children begin to explore the social world outside their own home. Group socialization theory of development (Harris 1995) asserts that parents do not play as big a role in their children's development as was once thought, because peer pressure plays a more important role that was first realized. A child is socialized outside the home through two processes: identification with a peer group and assimilation of group norms. Peer pressure functions less as an incentive to conform and more as an incentive to be involved in activities which are perceived to be relevant to one's identity within one's peer network.

Some seminal experiments showed that the presence of peers may induce behaviors approved of by the peer group. For example, adolescents make riskier decisions and to engage in greater risk behaviors when their peers are present (Gardner and Steinberg 2005). In addition, if adolescents have friends who show deviant behavior, they are more likely to display externalizing behavior themselves (Goodnight et al. 2006). The presence of peers may also induce prosocial behaviors (van Hoorn et al. 2016). In summary, peer-approved behaviors increase when peers are present. This peer-effect arose through natural selection and now all humans have an innate, subconscious response to peer pressure.

Peer Pressure and Mating

The sources of peer pressure vary over the lifespan. From middle childhood, individuals have to prepare to cope with the pressures

surrounding mating (Chen and Chang 2012; Del Giudice 2009). Furthermore, gender differences in peer pressure emerge during adolescence and adulthood. Men are more susceptible to peer pressure relating to social status and dominance, whereas women are more susceptible to peer pressure relating to physical appearance (e.g., clothing selection, body shape or size and hairstyle).

Men are more likely than women to experience the competitive pressure from the same-sex peers and also more likely to adopt dominance-relevant strategies (e.g., aggression) in intrasexual competition (Chen and Chang 2015). Women also compete for mates. Peer pressure applies in the digital world as well as in traditional face-to-face encounters. Social media can be used to exert pressure on peers in their daily life (Ferguson et al. 2011).

Conclusion

Peer pressure is part of human life. I briefly discussed the associations between peer pressure and child development and between peer pressure and mating. Children are vulnerable to peer pressure. There are sex differences in the effect of peer pressures on mating strategies that stem from sex difference in intrasexual competition.

Synonyms

Gender; Ostracism; Social exclusion; Social rejection

Definition

Peer rejection Peer rejection is a negative social event in which an individual is deliberately excluded or isolated by his or her peers from social interaction or from social relationships.

Introduction

Human beings have an innate need to belong (Baumeister and Leary 1995). When an individual experiences rejection, he or she may therefore experience a variety of negative psychological, physiological, and/or behavioral outcomes. There are various forms of social rejection that lead to these negative outcomes, such as rejection by family members, rejection by potential or current romantic partners, and rejection by peers in which an individual is rejected by those who are theoretically the individual's social equals. This entry will focus exclusively on gender differences in responses to rejection by peers.

Although most people experience peer rejection as negative, responses to social rejection may differ based on dispositional traits of the rejected individual. One such moderating factor that has been examined in prior research is gender. Although most research examining gender as a moderating factor has not found statistically significant gender differences in participant responses to peer rejection (e.g., Forney et al. 2005; Flook et al. 2005; Nolan et al. 2003; Nesdale and Lambert 2007; Weiner and Handel 1985), a handful of studies have found significant differences between how males and females respond to rejection by peers. We discuss these differences below in relation to psychological detriments, physiological detriments, and behavioral outcomes.

Psychological Detriments

Several studies have examined gender differences in psychological reactions to peer rejection. One study found that although shy males reported significantly greater negative affect than

nonshy males following peer rejection, this difference was not found between shy and nonshy females (Howarth et al. 2013). Another study (Zimmer-Gembeck 2015) examined coping skills following peer rejection, such as avoidance of future social situations, rumination about the rejection incident, seeking social support post rejection, distraction from the social situation (e.g., engaging in a fun activity, reading a book, watching television), or opposition toward those who rejected the individual. After experiencing rejection, females reported more rumination, distraction, and social support seeking than did males. Males, however, reported greater opposition than females, specifically thinking about seeking revenge toward those who rejected them (Zimmer-Gembeck 2015). These findings could be explained by the work of Rose and Asher (1999), who found gender differences in how males and females cope with conflicts with their friends. Females were more likely to accommodate and compromise than males during a conflict, whereas males reported greater hostility and aggression than females during a conflict with a friend.

Other research conducted by Baldwin et al. (2003) suggests that peer rejection may be more psychologically detrimental to females than to males. Examining self-critique following peer rejection, rejected females reported increases in negative self-critique (e.g., using more words like “worthless,” “stupid,” or “inadequate” to describe themselves), decreased self-esteem, and increased negative affect. Rejected males, however, reported significantly more positive outcomes than rejected females, such as increased positive affect and increased self-esteem (Baldwin et al. 2003). Although this outcome was novel in terms of peer rejection, previous research shows that females tend to be more self-critical than males and that males tend to be more positive than females following negative events. For instance, one study reported that, in general, females are significantly more self-critical, exhibit greater interpersonal vulnerability (e.g., experiencing helplessness without social support), and report more internalizing problems (e.g., anxiety and depression) than males

following negative self-relevant events (Leadbeater et al. 1999). Furthermore, when examining other areas of stress (e.g., financial stress), men reported more optimism and positive affect than female participants (Jacobsen et al. 2014). Additionally, previous work has reported that males engage in significantly more self-compassion than females (Yarnell et al. 2015). The findings reported by Baldwin et al. (2003) are therefore consistent with other research examining gender differences in responses to negative events.

Moreover, females who experience ostracism or ambiguous exclusion from a group are more likely to believe the ostracism was in response to their own poor character than males, meaning they are more likely to believe that the ostracism was their fault (Williams and Sommer 1997). These findings relate to previous research examining gender differences in response to negative feedback. When interpreting negative feedback from a work assignment, females tend to view negative evaluations as accurate and serious, whereas males tend to view negative evaluations as inaccurate and unimportant, even going as far as to condemn the person evaluating them (Johnson and Helgeson 2002). Although rejection is not an overt negative evaluation, it can indicate that those rejecting the person do not value their relationship with that person. As a result, the way in which males and females respond to peer rejection is relatable to the findings reported by Johnson and Helgeson (2002) in the sense that rejection from a peer group may be an indication of a negative social evaluation.

Physiological Detriments

Although most research examining responses to peer rejection has focused on the psychological detriments of rejection, physiological detriments have also been examined in response to peer rejection. Furthermore, gender differences have been found in physiological responses to rejection. For instance, Stroud et al. (2002) found that females exhibit significant increases in salivary cortisol concentrations following peer

rejection whereas males do not (Stroud et al. 2002). To replicate the findings from Stroud et al. (2002) and to add additional physiological measurements of the hypothalamic pituitary adrenocortical (HPA) axis and of the autonomic nervous system (ANS) stress responses, Stroud et al. (2017) examined physiological responses to peer rejection in pre- and post-puberty males and females. They found that post-puberty females exhibited a significantly greater physiological stress response following peer rejection than pre-puberty females, pre-puberty males, and post-puberty males (Stroud et al. 2017). Peer rejection can, furthermore, affect heart rate reactivity. For women exposed to peer rejection in an online simulated game, heart rate reactivity significantly decreased from baseline measures (Sijtsema et al. 2011). This decrease, while also found in males, was more pronounced in females (Gunther Moor et al. 2014). Thus, research suggests that females may experience more detrimental physiological responses to peer rejection than males.

Behavioral Outcomes

Alongside psychological and physiological detriments, research has reported gender differences in behavioral responses to peer rejection as well. Females experiencing peer rejection reported engaging in more relational aggression than males (e.g., spreading gossip about peers, verbal bullying, not playing well with others; Sijtsema et al. 2011). Males, however, report engaging in more physical aggression after experiencing peer rejection (e.g., pushing, hitting, kicking, biting) than females (Kawabata 2016). Additionally, McEachern and Snyder (2012) found that peer rejection mediated the relationship between physical aggression of boys in kindergarten and covert antisocial behavior when those same boys were in the first grade. Moreover, individuals who experience peer rejection at an early age displayed significantly more teacher-reported aggression than individuals who did not experience peer rejection. Although rejected males and females were reported to be more aggressive than their

nonrejected peers, teacher evaluations revealed that rejected boys were rated significantly more aggressive than rejected girls (McEachern and Snyder 2012). Therefore, not only can peer rejection have immediate consequences on behavior outcomes, but also longitudinal consequences in the form of covert antisocial behavior, at least for males.

Conclusion

The studies summarized above have shown gender differences in psychological, physiological, and behavioral responses to rejection by peers. Although males and females may report or exhibit differences in the experience of rejection, both males and females experience potentially detrimental outcomes that could affect them long-term.

It is important to note, however, that not all studies observing psychological, physiological, and/or behavioral outcomes of peer rejection examine gender differences (e.g., Anderman 2002; Bishop and Inderbitzen 1995; Martin and Cole 2000; Schwartz 2000) and that the majority of studies examining gender as a moderating factor did not find significant evidence for gender differences in response to peer rejection (e.g., Forney et al. 2005; Flook et al. 2005; Nolan et al. 2003; Nesdale and Lambert 2007; Weiner and Handel 1985). Aspects such as gender and societal norms, as well as social desirability, may be a mechanism by which gender differences in self-report and observational measures occur. In regard to psychological detriments, it is often more socially acceptable for females to report psychological distress in response to peer rejection whereas males may perceive that it is less socially desirable and weak to report psychological distress in response to peer rejection (Chandra and Minkovitz 2006). For observational measures with behavioral outcomes, it is a social normative for males to be more physically aggressive, whereas, in females, physical aggression is neither a desired nor normative behavior (Baillargeon et al. 2007). Therefore, researchers should examine and be aware of this desirability when

examining their own or others' work in which gender differences are found in responses to peer rejection.

and cooperated in social groups (Baumeister and Leary 1995). Yet competition for status and resources also exists within a group, and this can lead to hostility and exclusion. Research has found that peer rejection is likely to occur when a person deviates from prevailing group norms (Juvonen and Gross 2005). Individuals who are too boisterous, too shy, or too studious are at greater risk. This suggests that in addition to competitive motives within the status hierarchy, peer rejection may have the additional purpose of maintaining conformity and cohesiveness in the group. When rejection occurs, it can take a variety of forms, from passive avoidance to active, physical threats (Asher et al. 2001). Three general categories of aggressive rejection behaviors have received the most research attention. These consist of physical aggression, verbal aggression, and relational aggression. Sex differences have been found in each of these categories of behavior.

Peer Rejection, Sex Differences in Initiation of

J. Corey Butler
Southwest Minnesota State University,
Marshall, MN, USA

Synonyms

Interpersonal rejection; Social rejection

Definition

The deliberate exclusion of an individual from friendships, groups, or social interactions by peers of similar age and social position.

Introduction

Humans are social animals and have a fundamental need to be accepted by others. This need to belong may have evolved from advantages in survival and reproduction that would have been conferred upon ancestors that lived

Varieties of Rejection

Physical aggression consists of overt rejection behaviors involving potential physical harm (e.g., hitting, pushing), as well as damage to personal property. Studies have consistently found that across age groups and cultures, males exhibit more physical aggression than females (Archer 2004). This is one of the most robust sex differences to be documented in the research literature. Ironically, individuals who engage in highly aggressive behavior are often more likely to be rejected themselves. Verbal aggression, on the other hand, includes threats, name-calling, insulting remarks, taunting, and related behaviors. As in the case of physical aggression, males engage in more verbal aggression than females, but the difference is not as large (Archer 2004). These sex differences are consistent with sexual selection theory, which states that across many species, males have evolved to be larger and more aggressive in their behavior as a result of competition between rivals.

Physical and verbal aggression are relatively direct forms of social rejection. Relational aggression, however, is more indirect. Relational

aggression includes spreading rumors and gossip, ignoring or excluding individuals from activities, and otherwise undermining reputations and relationships. There is evidence that females are more likely to engage in relational aggression than males. For example, women are more likely to gossip about others, whereas men are more likely to talk about themselves (McAndrew 2014). Sex differences for relational aggression are less consistent than they are for the more direct approaches (McEachern and Snyder 2012), possibly because of the greater variation in behavior that falls under this category. Nevertheless, a tendency for females to be more likely to utilize indirect, relational aggression is consistent with the well-established finding that females have a lower tolerance for risk taking (Byrnes et al. 1999).

Cyber Rejection

Cyberbullying refers to activities such as threats, harassment, and rumor spreading that are carried out via cell phones, social media, and other electronic technologies. In terms of our previous distinctions, this form of peer rejection may involve either verbal or relational aggression. Cyberbullying is a growing problem in our ever more electronic world, yet it is less common than traditional bullying, and there is a substantial overlap among perpetrators of cyberbullying and other kinds of bullying (Modecki et al. 2014). Preliminary research has not found consistent gender differences in overall frequency of cyberbullying, but there is evidence that females who initiate rejection are more likely to turn to cyber bullying (Slonje et al. 2013).

Conclusion

Peer rejection is a universal human experience and an inevitable aspect of living in groups. Mechanisms for exclusion and ostracism likely evolved alongside of our tendency toward social affiliation (Leary and Cottrell 2013). Rejection occurs across age groups and gender, and nearly

everyone will suffer from a rejection experience at some point in life. Despite this prevalence, certain patterns of rejection behavior are more typical than others. Males are more likely to engage in direct aggression when initiating rejection, both physically and verbally. Females are more likely to initiate indirect or relational forms of rejection. These differences are consistent with evolutionary theory as well as traditional gender roles. Although potentially hurtful to individuals, peer rejection serves various group purposes, such as cohesiveness, resource management, and the delineation of relationships and status hierarchies.

Synonyms

Friendships; Peer acceptance; Peer groups; Peer networks; Peer rejection

Definition

Peer relationships are the social bonds that tie together two or more individuals who are similar in age or social group.

Introduction

Relationships matter for youth. They matter for young people's well-being, impacting development, health, achievements, and overall life satisfaction. Relationships may take many forms, but

relationships with peers are among the most important and influential relationships in young people's lives. Relationships with peers, or others who are similar in age and/or social group, can be quite diverse. Some peer relationships are close and tightly knit, involving a small number of peers who form a strong bond with one another. Other relationships are more diffuse and involve many peers who share ties or connections to one another. Relationships can be positive – characterized by liking, support, and trust. They can also be negative – characterized by disliking and harm. Relationships can be hierarchical, with one or more members of the relationship leading or dominating others, and they can be egalitarian, in which leadership, power, and control are shared. Thus, a best friendship, in which two peers form a supportive, trusting bond with one another, a gang of youth who repeatedly come together to victimize others, and a classroom of children in which some set the norms for how to act and others follow those norms are all examples of peer relationships. As these examples hint, youth can have multiple peer relationships. Some relationships are embedded within others. For instance, close friends might be embedded within a larger social group. Others are distinct, as when a child is friends with one peer but enemies with another.

In this chapter, we explore peer relationships in childhood. In doing so, we consider their evolutionary significance and the ways in which peer relationships both change and remain the same as children grow up. We also address the fact that peer relationships are defined by the competencies and motivations that each child brings to the relationship as well as by the characteristics of the relationship as a whole. As we explain how relationships develop and evolve as a function of what individuals bring to the relationship and how the relationship as a whole entity is structured, we suggest that these factors can move relationships down more, healthy and effective pathways as well as down more unhealthy and ineffective pathways. We conclude by discussing the impacts of positive and negative peer relationships on children's lives and providing recommendations for ways to promote positive peer relationships among children.

The Evolutionary Significance of Peer Relationships

The fact that peer relationships are evident at all ages, even among the very young, hints that there may be evolutionary processes at play in the development of peer relationships. Indeed, evidence from animal studies shows that many species engage in social activities (such as play) and develop relationships with peers. Rhesus monkeys, feral pigeons, bottlenose dolphins, and whales are examples of animal species that, similar to humans, engage in social activities with peers (Amos et al. 1993; Connor et al. 2000; Giraldeau and Lefebvre 1987; Ruppenthal et al. 1974). Although peer relationships are common in many animal species, rhesus monkeys' peer relationships have received a great deal of attention because of the genetic, physiologic, and metabolic similarities between rhesus monkeys and humans (Roth et al. 2004). Thus, there is much to be learned about human behavior and functioning by studying rhesus monkeys. Several aspects of peer relationships that are evident in rhesus monkeys are also evident in humans. For instance, rhesus monkeys begin to engage in peer relationships early in life, just as young human children do. Moreover, like humans, rhesus monkeys continue to engage with peers at high rates into adolescence (Ruppenthal et al. 1974). Peer relationships can provide a forum for engaging in recreational activities as well as work activities that are needed to accomplish goals (Coolahan et al. 2000; Roseth et al. 2008). For both humans and monkeys, this could include, for example, playful interactions, grooming activities, collecting food and water, or exchanging goods (Bernstein 1970; Hassett et al. 2008; Suomi 2005). Further, like humans, rhesus monkeys' peer play becomes more gender specific and gender segregated, and involves more complex behavioral sequences as development occurs (Mehta and Strough 2010; Suomi 2005). That is, both rhesus monkeys and humans tend to play with same-gender peers, with males playing with other males and females playing with other females. They tend to engage in more social behaviors that are typical of their own gender,

and fewer social behaviors that are typical of the other gender (Berenbaum et al. 2008). And, with development, both rhesus monkeys and humans engage in increasingly sophisticated behaviors (Sackett 1972; Yang et al. 1995). The time spent with peers is useful because it provides a platform for learning valuable skills.

The fact that peer relationships are ubiquitous across species suggests that peer relationships are evolutionarily adaptive – or that they have evolved over time to promote the well-being of members of the species. Indeed, this is true. Peers are responsible for providing opportunities for individuals to develop skills that help to ensure their survival (Giraldeau and Lefebvre 1986; Suomi 2005). This is important for young individuals, as it is the primary job of youth to learn what is needed to live a healthy, successful, and well-adjusted life. This makes the development of peer relationships vital. For example, in young squirrel monkeys, play fighting, which involves dominant and subordinate monkeys wrestling with each other and attempting to pin each other to the ground, is common (Biben 1998). This supports the establishment of defense skills that are needed to protect the monkeys when they get older. Young children do the same thing; rough-and-tumble play, which is an active, physical play that can involve pretend fighting, is common, particularly for boys (Smith and Boulton 1990).

Not only is there an evolutionary basis for engaging in peer relationships, but there is also an evolutionary basis for how peer relationships may be structured and organized. Studies of domesticated pigs, for example, have shown that peer relationships are often hierarchically organized according to status or dominance (Meese and Ewbank 1973). When relationships with peers are hierarchically organized, those members of the peer group who are higher in status (e.g., strongest) have power over those who are lower in status. This power enables high status peers to obtain more resources or better resources (such as food, opportunities for potential mates) than their lower status peers. In this way, status within the peer group confers an advantage. To illustrate, studies of chimpanzees have shown that chimpanzees' status in the hierarchy is directly related

to food and reproductive success (Wittig and Boesch 2003). Similarly, dominance hierarchies can emerge among human youth. Youth may selectively use coercive and aggressive (e.g., talking about a peer behind his/her back; excluding a peer from a social activity) as well as pro-social behaviors (e.g., complimenting a peer or inviting him/her to an event) to maintain their own social status, to elevate their social power towards selfish goals, or to diminish another's social status (Hawley 1999, 2003). When targeted selectively at relatively high-status peers, this can increase one's own status. It is important to note, however, that even though having high status among peers can enable youth to obtain valued resources (such as invitations to social activities or preferred opportunities) it can also come at a cost. High status youth may be targeted for victimization by other high-status youth, and high-status youth are not necessarily well-liked by others (Andrews et al. 2017). Moreover, youth who find themselves lower in the hierarchy can suffer (Parker and Asher 1987). As we explain later in this chapter, social structures that enable youth to be more egalitarian and interconnected tend to produce adaptive outcomes for all children without significant costs (Cochran and Brassard 1979).

A Developmental Perspective on Peer Relationships

In humans, peer relationships begin to emerge in infancy and early childhood as very young children are first exposed to peers, and they extend across the lifespan into late adulthood. To be more specific, friendships are evident at all ages. Children at all ages can identify peers whom they like and those whom they dislike. Children at all ages form stronger social bonds with some peers and weaker ones with others. Thus, there is remarkable similarity across ages in the existence of peer relationships (Noller et al. 2001).

Beginning in the first years of life and continuing across the lifespan, individuals interact with one another. Interactions provide the building blocks upon which peer relationships develop.

Interactions can be simple, involving subtle non-verbal behaviors, such as eye contact or a smile. Although such subtle behaviors might seem insignificant, even a gaze can signal interest, engagement, and the potential for more in-depth interactions (Vaughn and Waters 1981). Similarly, behaviors such as parallel play – in which two or more peers participate in the same activity side-by-side – can provide a forum for more involved interactions to occur (Bakeman and Brownlee 1980). For instance, playing an electronic game next to another child who is playing the same game can lead to direct interaction, such as sharing of ideas. Interactions can be simple, such as brief exchanges (e.g., making and responding to a simple request), and they can be complex, rich, and reciprocal, such as extended conversations or participating in intricate, rule-based games (Fabes et al. 2009). Regardless of their complexity, each interaction sets the stage for the next, and over time, relationships are dynamically built. Thus, peer relationships can grow and change over time.

The complexity and sophistication of peer interactions changes with age. For infants and toddlers, whose physical, linguistic, cognitive, and social skills are still rudimentary, children begin to learn about peer relationships by observing others (Rubin et al. 2005). By watching social interactions, children develop a general understanding of peer relationships, soaking in information about how to interact and the effects of interactions (Bandura and Walters 1963). Moreover, by paying attention to how others respond to their own behaviors (e.g., gazing, smiling, crying, physical acts, statements, questions), young children begin to form relationships of their own. As children get older, new physical, linguistic, cognitive, and social developments allow children to become more and more sophisticated in how they communicate their emotions, desires, interests, and needs in social situations and in how they respond to others. This can be seen in the increasing complexity of children's interactions with peers – for example, nonverbal interactions that are characteristic of young children are augmented by verbal ones as children get older, simple statements or requests of peers are expanded by extended conversations, and the factors that

bring peers together develop from basic commonalities to include deeper and richer ones, such as mutual sharing, trust, and support (Fabes et al. 2009). Moreover, as children's interactional skills develop, so does the complexity of their relationships. Early relationships are fairly simple, typically involving straightforward interactions with a single peer. As children grow, their abilities to manage larger groups of peers and multiple peer groups also evolves (Strayer and Santos 1996).

The development of peer relationships is important because early relationship experiences set the stage for later relationship experiences. Thus, children's relationship experiences in early childhood – namely, the extent to which children have relationships with peers, the breadth of those relationships, and the nature and quality of these – impact their likely relationship experiences in middle childhood. In turn, these lay the foundation for the kinds of relationships that adolescents have with their peers. For this reason, one might see continuity in peer relationships, such that those who have many positive relationships early in life are also those who are well-connected with peers in positive ways later in life. Similarly, those who are withdrawn from peers and those who have conflictual peer relationships early on might continue to struggle in their peer relationships later (Hay et al. 2009). Yet, early relationships are not deterministic. Changes are certainly possible, and children can move from more challenging to more rewarding relationships as they learn and grow with practice, motivation, and support (Cairns et al. 1995; Coplan and Arbeau 2009). Indeed, we next consider factors that contribute to more and less effective relationships, and we conclude this chapter by providing suggestions for building effective peer relationships.

Determinants of Peer Relationships

What determines peer interactions and, consequently, peer relationships? This question has often been asked by children, the adults who work with them and support their development, and the scholars who study peer relationships. In answering this question, it is important to

remember that relationships are made up of multiple (two or more) individuals. Each individual brings his or her own competencies, motivations, and characteristics to the relationship and, in doing so, the relationship reflects aspects of each person while also being greater than the sum of its parts. In this way, the relationship is a unique entity and any one individual will have different relationships with different peers. In the sections that follow, we take a closer look at these two important factors: (1) the competencies and motivations that individual children bring to their relationships and (2) the relationship as an entity that exists among two or more peers.

Relationship Competencies and Motivations of Individual Children

The nature and quality of peer relationships are determined, at least in part, by the competencies and motivations that individual children bring to their peer experiences. This includes children's social and emotional skills. Social and emotional skills are those skills that contribute to effective (versus ineffective) peer interactions. Included in this list are such skills as emotion recognition and emotion display skills (the ability to accurately identify one's own and others' emotions and to present one's own emotions in ways that are modulated and appropriate for the situation); decision-making and problem-solving skills (the ability to identify and resolve problems, to make decisions about how to proceed in complex situations, and to evaluate the success of one's decisions); perspective taking and empathic skills (the ability to understand what another might think or feel and why he or she might think or feel a certain way); and communication skills (the ability to effectively listen to and respond to others' points of view and to express one's own) (Weissberg et al. 2013). Each of these skills is important to relationships because they enable individuals to understand their own needs, goals, and desires as well as those of others. They also enable members of the relationship to work toward establishing common goals that are shared by all. Thus, effective social and emotional skills contribute to effective peer interactions and, as a result, effective relationships. In contrast, ineffective social and

emotional skills contribute to ineffective peer interactions and, as a result, ineffective relationships (Rubin et al. 1998).

Also important are the attitudes and beliefs about relationships that each individual brings to the relationship. The behaviors that children exhibit when with their peers do not emerge out of a vacuum; rather, they are influenced by the perceptions that children have about relationships. For instance, some children feel efficacious or comfortable in their interactions with others, expecting that they will have positive and supportive experiences; others may feel inefficacious or uncomfortable, expecting negative experiences and outcomes (Zosuls et al. 2011). Children (like adults) hold attitudes, biases, and stereotypes about others, and these guide their interactions (Abrams et al. 2007). Children's interpretations of social experiences and explanations for their own and others' behavior (such as: "he did that on purpose" or "it was just an accident") can affect the tone of an interaction (Crick and Dodge 1994). Each of these attitudes and beliefs have the potential to promote either positive interactions and relationships or negative ones, thereby influencing the likelihood of a relationship forming as well as the nature and quality of that relationship.

The competencies and motivations that children bring to their relationships are important because they contribute to the affective tone of the relationship. Children vary in their relationship competencies and motivations. In other words, children who have more positive and effective skills and those who are more interested in and motivated toward building relationships tend to have more enjoyable, understanding, supportive, and trusting relationships than those whose skills are less well developed or who may be more reticent to engage with others. In the latter case, children may find themselves relatively isolated from their peers, challenged to connect with others, or in relationships marked by disliking, aggression, and mistrust. Importantly, relationship competencies and beliefs can be taught and learned. They can be learned in the context of interactions with other children, observing how others behave, practicing new skills, and receiving feedback about how their interactions are

perceived by others. Parents, teachers, and other supportive adults (e.g., grandparents, coaches) can also model relationship skills and beliefs and they can directly teach these to children. In fact, programs that teach relationship competencies (such as those implemented in schools) can be effective in building social and emotional skills and in expanding and improving relationships. Moreover, the positive effects of teaching effective relationship skills add up, leading to benefits in other areas, such as academic achievement and health (DeLay et al. 2016; Durlak et al. 2011; Miller et al. 2017).

Relationships as an Entity

Relationships can exist among two peers (known as a dyad) or more than two peers (known as a group). Groups can be small (made up of three or four peers) or large (for example, all of the students in a class). The size of the relationship is one indicator of how the relationship is structured. Another indicator of how the relationship is structured is the degree to which the members of the relationship are interconnected with one another. This becomes an increasingly important indicator of the structure of the relationship as groups get bigger in size. To illustrate what this means, consider a large group (for example, a class of students). If most of those students have strong ties to one another, that is, if most are friends with (or, at a minimum, friendly toward) most others then the group as a whole is likely to function well. In this case, few peers (if any) will feel left out of the large group peer relationship. And, the circumstances will be present to allow for egalitarian peer relationships, or those in which status, power, and leadership are relatively equally distributed and shared. In contrast, in a large group that is characterized by a lack of interconnectedness, the ties that bind peers together are weak. The large group is fractured, and many may feel disconnected and left out. When this happens, some may rise to the top of the group gaining more status and power than those who fall near the bottom of the hierarchy (Rodkin and Gest 2011). This type of relationship structure can be harmful because children jockey for position and status in a fractured peer network. This creates conditions

that are ripe for negative peer relationships to occur, such as those in which bullying and victimization are common (Ahn et al. 2010; Serdiouk et al. 2015). Thus, the structure of the peer relationship can impact the quality of children's peer experiences, just as can the individual competencies and motivations that children bring to their relationships.

Moving beyond the structure of the relationship, we also consider the constitution of the relationship. Often, relationships form among peers who are similar to one another. For instance, relationships may form among peers who are similar on gender, behavioral styles (such as aggressive or prosocial behaviors), interests, and even indicators of healthy functioning (such as depression or academic motivation) (Fabes et al. 2003; Kindermann 1993; Prinstein 2007). Thus, girls often form relationships with other girls, aggressive children spend time with other aggressive children, academically motivated youth connect with other academically motivated youth, and so on. This tendency is known as homophily. It is often driven by the children themselves, as they gravitate towards others who appear to be similar (Serbin et al. 1994). Homophily can also be reinforced by peers or adults as an appropriate basis for friendships, just as relationships with those who are different can be discouraged by peers and adults (McPherson et al. 2001).

Homophily is evident in peer relationships beginning in early childhood (Hanish et al. 2005). Thus, by the time children are aged 3–4 years, they tend to segregate themselves in relationships with other similar peers. Homophily does not disappear as children get older; this is a common feature of peer relationships across development, and it is demonstrable in middle childhood, adolescence, and into adulthood (Aboud and Mendelson 1996). Although we often think of homophily as relevant to positive relationships, such as friendships, it is important to note that homophily can just as readily occur in negative relationships, such as bully-victim relationships. Indeed, it is more likely that boys and girls aggress against same-gender peers than it is that they will aggress against other-gender peers (Russell and Owens 1999).

Such segregation in relationships is important to recognize when it occurs because it has effects on the relationship itself as well as on the individual participants in the relationship. Relationships with similar peers form readily. For instance, even when first meeting a new peer, those who are similar to one another tend to cooperate more and like each other more than those who are dissimilar (Andrews et al. *in preparation*). As relationships develop, children become more like one another over time via a process known as peer influence. Children model behaviors for one another and reinforce each other's behaviors (Prinstein 2008). When children are in relationships with similar peers, they tend to encourage one another to become even more alike. Thus, boys who spend more time with boys become even more masculine in their behaviors as compared to those boys who spend less time with other boys, and this is especially true for those boys who are most masculine at the beginning (Martin and Fabes 2001). Similarly, aggressive and delinquent children and adolescents who spend time interacting with other aggressive and delinquent peers become more aggressive and delinquent over time (Dishion et al. 1996; Hanish et al. 2005). And, children who behave prosocially become even more prosocial when they spend time with similar peers (Carlo et al. 1999). In other words, spending time with those who are similar to oneself increases the strength and impact of the factors that drew similar peers together in the first place.

Clearly, homophily is a common feature of peer relationships. But, is it the rule? In other words, might relationships form among youth who differ on key dimensions? For instance, might girls and boys form friendships? Might children of different racial and ethnic groups build relationships? Is it possible that aggressive and nonaggressive youth interact? These are important questions for those who want to broaden children's experiences and skills by encouraging a well-rounded set of peer relationships. The answer to all of these questions is *yes*. Although homophily is typical of peer relationships, relationships can also form among youth who might appear to be different from one

another. Take the example of gendered relationships. Children respond more positively to same-gender peers, they interact more with same-gender peers, and they are more likely to be friends with same-gender peers (Fabes et al. 2003; Hayden-Thomson et al. 1987; Howes et al. 1988; Kupersmidt et al. 1995). Yet, interactions and relationships can also occur among other-gender peers. The findings of one study, for instance, showed that interactions with only same-gender peers (girls interacting only with girls or boys interacting only with boys) occur about 60% of the time in preschool classes. For the remaining 40% of the time, children interacted with members of both genders simultaneously (30% of the time) or solely with those of the other gender (10% of the time) (Fabes et al. 2003). These data show that, despite a preference for same-gender peers, opportunities for interacting with and developing relationships with other-gender peers are readily available. The same can be said of other dimensions on which children might select peers.

Moreover, nonhomophilous relationships – or those in which members of the relationship differ in important ways – are valuable and should not be overlooked. In fact, they should be encouraged as such relationships are consistent with an inclusive attitude that is accepting of diversity and inconsistent with an attitude of exclusion. It is important to say that homophilous relationships are not necessarily problematic in and of themselves. Indeed, spending time with similar peers can have positive effects by, for example, increasing positive emotions (e.g., happiness, joy, satisfaction; Martin and Fabes 2001). The lack of relationships with those who are different from oneself, however, is problematic. This is because diversity in relationships provides opportunities for children to develop needed social competencies that are critical to effective interactions across the lifespan. Consider again the example of gendered relationships. When relationships are gender-segregated, children learn the interaction styles and skills that are most typical of their own gender, which leads to feelings of comfort with same-gender peers. Yet, children miss out on opportunities to learn the interaction styles and

skills that are more typical of the other gender, which can lead to feelings of discomfort with other-gender peers (Zosuls et al. 2014). And, over time, the lack of understanding of and comfort with other-gender peers can lead to more serious problems, such as biases against other-gender peers, stereotyping by gender, and harassment and bullying of others for gendered reasons (Fabes et al. 2013; Hunt and Gonsalkorale 2014). Similar problems can also arise when children's peer relationships are limited to homophilous peers on dimensions other than gender. Furthermore, when relationships are focused on others who are homophilous on behaviors that are generally problematic (such as aggressive behavior), the consequences that arise from the lack of exposure to others who encourage more positive interactional styles can be even more detrimental (Hanish et al. 2005).

Thus, providing children with opportunities and support for developing relationships with a wide array of peers is optimal for their development and well-being. That is, relationships with peers are good, having relationships with many peers is good, and having relationships with a variety of peers is good. In the next sections, we delve more deeply into relationships by considering the quality of relationships, how quality can vary, and why the quality of relationships matters. We conclude by providing simple suggestions that can help to build positive peer relationships among children.

Quality and Impact of Peer Relationships

Peer relationships can vary greatly. Some individuals have relationships with many other peers whereas others have a more limited set of peers in their social circles. For some, positive relationships (for example, characterized by mutual liking, support, sharing, and understanding) abound; for others, negatively toned relationships (for example, characterized by conflict, aggression, and distrust) are more common. When peer relationships are strong, plentiful, and positive, children typically flourish. When they are limited or

absent and when they are negative in tone and quality, children may struggle.

Positive peer relationships are defined by mutual liking and acceptance of one another. Often, liking leads to friendships, which are strong bonds between children that involve perceptions of compatibility, companionship, trust, and mutual affection (Brownell and Brown 1992; Hartup and Stevens 1997). These fundamental aspects of friendship provide children with a feeling of belongingness, or the feeling that one fits in with others and is part of a group (Newman et al. 2007). Belongingness is important to human's need for frequent positive interactions with others and to feel cared about (Baumeister and Leary 1995). When children feel like they belong, they flourish, demonstrating greater self-esteem, experiencing increased opportunities for positive social experiences, and achieving in school (Buhrmester 1990; Cauce 1986; Deci et al. 1991; McGuire and Weisz 1982).

Indeed, involvement in positive peer relationships promotes positive developmental outcomes. That is, good relationships lead to a good life. From a social and emotional standpoint, having positive peer relationships promotes social and relationship competencies, such as prosocial behaviors, perspective taking, empathy, emotional well-being and positive self-esteem (Rubin et al. 1998). For instance, a study found that positive peer relationships among preschoolers impacts the use of negotiation to find a solution that works for all parties, over and above ineffective techniques, like disengaging from the interaction (Hartup et al. 1988). There are also benefits of positive peer relationships outside of social situations. For example, studies show that positive peer relationships in middle school children support better classroom engagement and performance on academic tests (Furrer and Skinner 2003; Liem and Martin 2011). Other studies have shown similar findings, with positive peer relationships being related to children's motivation to achieve in the classroom in addition to enhanced academic achievement (Wentzel 2003). Positive peer relationships also have an impact on health. By engaging in positive, effective peer relationships, individuals may have the opportunity to

better their psychological and physical health (Cohen et al. 2000). For instance, a study on adolescents with Type I diabetes showed that supportive peer relationships are related to greater self-care for those with the disease (Skinner et al. 2000). These outcomes lead us to believe that positive, effective peer relationships are a fundamental part of development.

Not all peer relationships are positive and supportive experiences, however. Some children may be withdrawn from or rejected by others and feel disconnected from the larger peer group. Moreover, negatively toned relationships, like those characterized by conflict, aggression, disliking, and distrust, can occur among youth. Indeed, some children are disliked, rejected, and victimized by their peers. In fact, children who are socially isolated are more likely than those who are closely connected to peers to be involved in aggressive and victimizing relationships (Ladd and Burgess 1999; Laursen et al. 2007). Further, being victimized can lead to increased social isolation (Rubin et al. 2009). In other words, social isolation leaves children vulnerable to peers' attack and peers' attacks can further isolate children. In such cases, the very children whose relationships with peers are most challenged can also retaliate with aggression of their own. Children who have multiple relationship problems tend to also have the most challenges (Schwartz 2000).

Children's relationship problems breed problematic outcomes such as diminished social skills, emotional difficulties, academic struggles, and health problems. To illustrate, studies have shown that children who are victimized in their peer interactions are more likely to experience peer rejection and loneliness (Crick and Bigbee 1998). They are also prone to higher levels of depression as well as lower self-esteem (Crick and Grotpeter 1996; Olweus 1993). Other problematic outcomes could also include reduced participation in classroom activities, diminished academic performance, and, even, dropping out of school (Buhs and Ladd 2001; Coplan et al. 2001). For instance, studies show that experiencing negative peer relationships in childhood is associated with voluntarily leaving high school before graduation (Berston 1960; Elliott and Voss 1974). Further, children's mental and

physical health can be affected (Cacioppo and Hawkley 2003; Halle-Lande et al. 2007; Paxton 1996; Rigby 2000). For instance, children's experiences with obesity are directly related to their treatment by peers (Pearce et al. 2002).

Building Effective Peer Relationships

As we have suggested thus far, peer relationships can take many forms. Many children will experience positive relationships with peers. But, some will also experience negative ones. Often, people wonder whether it is possible to help youth who are experiencing problematic peer relationships to have more positive experiences and, if so, what can be done. It is important to note that peer relationships are, indeed, moldable. For youth who are struggling with peer relationships, and even for those who are not, it is possible to improve peer experiences. Here, we outline three considerations to keep in mind when working to enhance peer relationships. These are: (1) build relationship competencies and motivations; (2) provide opportunities for children to engage in fun, joint activities with diverse peers; and (3) create a supportive environment in which adults are on board with the plans.

As we noted previously, relationship competencies and motivations are not set in stone; rather, they are modifiable. Children can improve their skills for interacting with others. Even children who generally interact effectively might find opportunities to further shape and refine their skills, leading to even more successful interactions in the future. This can happen via instruction (or teaching children how to effectively communicate, understand and respect diversity, problem-solve, and work effectively with one another); modeling (or demonstrating positive interaction skills); reinforcement of positive interactions (or providing children with positive recognition for their efforts); and practice. Many schools have recognized the benefits of teaching such skills to children (Durlak et al. 2011). With this in mind, they have implemented social and emotional learning programs that help children to build the skills that underlie effective interactions.

Social and emotional learning programs are typically integrated into the school day and involve opportunities for children, with teacher support, to learn and practice the skills that contribute to healthy relationships. These programs have been shown to be effective (Miller et al. 2017). If such social and emotional learning programs are not readily available, children can still take opportunities to learn about relationship competencies from more knowledgeable adults or peers.

In addition to helping children to build relationship competencies, it is important to provide them with opportunities to engage with peers in enjoyable ways. These opportunities are most effective when they are structured equitably, so that all of the involved children are able to participate equally in an activity with shared goals. Indeed, for relationship-building to be successful, it is essential that the activities be ones that all peers agree with and are motivated for. These do not have to be complicated or demanding activities. They can be simple activities. For example, younger children might be given bubbles and asked to blow bubbles together or older children might try to work together to build a model. Activities can also be those that involve shared goals, such as group projects that provide each individual with opportunities to contribute. The point is that the participating children engage with one another in positive ways. Teachers, parents, or other adults can help support and guide children to ensure that the experiences are successful. To get the most out of this experience, it is important to pair or group children with a wide variety of peers, including those who are similar on key dimensions and those who are different. Peer partners can change over time, so that youth have opportunities to interact with multiple peers. Teachers, coaches, and other adults who work with youth can integrate these kinds of relationship-building opportunities in their everyday activities. Parents can also seek out opportunities to bring their children into contact with other peers in fun ways.

Finally, children will benefit from support in relationship-building from the adults in their lives. Relationship-building cannot happen, or, at least, it cannot happen effectively if adults are not on board. When adults value and prioritize positive

relationships, it communicates to children that relationships are important. Adults can let children know that they appreciate relationships by sharing this value and encouraging positive relationships. It is important to note that encouraging positive relationships is more effective than discouraging negative ones (Cialdini 2003). If adults direct most of their energy and attention to negative behaviors, even if they do so by telling children what not to do (e.g., “Do not hit”), they inadvertently put attention on problem behaviors. Instead, when adults focus on the positive and provide praise or other reinforcements when children interact well (e.g., “I liked how you listened when your friend was explaining what she wanted to do”), children are able to build a repertoire of skills. Adults can also communicate that they value positive relationships by using effective relationship competencies of their own when interacting with children and other adults.

Conclusion

The purpose of this chapter is to examine peer relationships in childhood. Children’s peer relationships are evolutionarily adaptive and important to their development and well-being. Children contribute to the nature and quality of their peer relationships by the competencies, skills, motivations, and expectations that they bring to their interactions with others. The resulting relationships, however, are also determined by the competencies, skills, motivations, and expectations that others bring. Many relationships are positive and healthy ones. These should be encouraged and supported. Although some relationship experiences can be problematic and challenging, children’s relationships with peers can be improved when caring adults support them in refining their social skills, provide opportunities to engage with others, and model and encourage effective relationships.

Introduction to Peer Socialization

The presence of peers is essential to human life as socializing is inherent to human nature (Hogan and Roberts 2004). Peers can be classified as individuals who surround us in our daily lives such as classmates, colleagues, friends, etc. Due to the fact that humans are constantly surrounded by peers during their lifetime, it is likely that peer interactions influence personality psychology. The core elements of personality are such: how we see ourselves (identity), how others see us (reputation), how we interact in social roles, and how identity, reputation, and interaction influence how we get along with others and achieve goals (Hogan and Roberts 2004). The latter two consider the impact of socializing on oneself.

Defining Peer Socialization

Peer socialization is the process in which peers can help one another develop skills that allow him or her to cooperate and act within set norms. Merriam-Webster defines peer as “one that is of equal standing with another; *especially*: one belonging to the same societal group especially based on age, grade, or status.” Peer socialization is most readily studied in childhood and adolescent relations but is a pervasive feature across our lifespan. It is commonly believed that peer socialization during early adulthood is often deleterious to personality development due to the influence of maladaptive behaviors (Choukas-Bradley et al. 2015). This, however, is not always true. Peer socialization is integral to personality development, especially during childhood and adolescence. Although personality is not thought to undergo dramatic change during adulthood (McCrae 1993), personality changes related to prosocial behaviors have been observed in adulthood (Hoerger et al. 2014).

Homophily in Social Groups

Peers tend to form into social groups based on similarity in individual characteristics. This is the principle of homophily (McPherson et al. 2001).

When it comes to forming social network groups, race and ethnicity are an important factor. People are more likely to discuss important matters with members of the same race. Gender and sex also influence social group preferences. Children are taught that gender is a personal characteristic upon entering school (McPherson et al. 2001). Therefore, younger children tend to interact with members of the same gender. However, upon entering adulthood, relationships become more gender-integrated. On the other hand, adolescence marks a time where teenagers are more likely to associate with those who share similar behavior patterns (McPherson et al. 2001). During this time patterns of prosocial and antisocial behaviors may become clustered within social networks. The notion that peer socialization is deleterious to personality development stems from the fact that teenagers are often subject to peer pressure and antisocial behaviors (Choukas-Bradley et al. 2015). Behavioral homophily is also present among adults, as they tend to associate with those of the same political practice and orientation (McPherson et al. 2001).

Mate Selection

Humans generally exhibit assortative mating patterns. Individuals with similar personality traits often choose each other as mates. Research shows a positive correlation between personality variables between spouses (Buss 1985). Mating with someone who possesses similar genes results in offspring that is 50% related to each parent and further related by the amount of genes the parents shared in common (Buss 1985). Therefore, because peers usually share similar characteristics, and individuals are likely to find a mate within his or her peer group, this may increase likelihood that offspring will share common traits with parents.

Group Socialization Theory on Personality Development

Group socialization theory states that socializing within peer groups is critical to personality development. Children have many environments that

they must learn to function in. The at-home environment forces children to build relations with parents and siblings. These relationships are much different than the ones made outside the home. The theory posits that children learn to function outside of the home by partaking in social groups (Harris 1995). Within social groups, children learn assimilation and differentiation. Assimilation is the adoption of set social norms which results in peers becoming more similar to one another. Differentiation increases characteristic variability (make groups dissimilar from one another). Assimilation and differentiation show themselves depending on differing social context and are not mutually exclusive. Group socialization theory concludes that at-home relationships are not influential to personality development. In fact, Harris proposes that siblings differ in personality not only because of genetics, but because of socializing within different peer groups (1995).

Conclusion

Peer socialization is a critical aspect of personality development because it teaches one how to function in society. Children are first exposed to peer groups during school where they learn about gender and sex. These factors tend to drive the way peer groups are assembled until adolescence. Adolescents tend to socialize with peers who share similar behaviors. Adulthood is where peer groups become increasingly gender-inclusive but still dependent on homophily. In fact, all age groups build social networks on the basis of homophily, the tendency to associate with similar individuals. Personality development begins during childhood and is heavily influenced by peer social groups outside of the home, not by family. Peer groups exist in adulthood as well but are less impactful to personality at this stage (Harris 1995).

Definition

Peers are defined as individuals of the same age and status.

Introduction

Peers play a prominent role in adolescence, the time between the onset of puberty and achieving independence from one's family of origin, roughly mapping into the second decade of life. Compared to children and adults, adolescents spend more time with peers, enjoy peers' company more, and consider peer norms as more important. This heightened importance of peers is highly conserved across species. For example, adolescent rats spend more time investigating and interacting with peers, and peer behavior is instrumental in learning and practice of adaptive and adult-like behaviors. Although peer influences can be positive (e.g., academically successful friends can motivate youth to work harder at school), more prevalent are concerns about peers' role in adolescents' problem behaviors. Indeed, peer influence is a key contributor to a variety of risky behaviors occurring in adolescence, such as delinquency, risky driving, unsafe sex, and substance use. Some of these peer influences occur through direct modeling of specific behaviors and/or providing opportunities for the behaviors to occur (e.g., observing peers smoke cigarettes or going to a party where alcohol and drugs are available). Other times, peer influences occur indirectly through teens' perceptions of what behaviors are normative or valued within the larger peer group (e.g., believing that most other teens are having sex and not having sex makes one inferior). And sometimes the mere presence of peers is sufficient to increase adolescents' risky behavior. For example, in one study the presence of peers doubled risky driving among early adolescents, although it did not affect driving behavior among adults (Albert et al. 2013).

to become competitive for sex and reproduction. Peers, as prospective mates and competitors, play a key role in this process. Spending time with peers away from adult supervision allows youth to strive for status in the peer group, explore their mate preferences, and practice mate-attracting strategies. The underlying biological changes of puberty support this process by creating reproductive capacity and competitive competencies (e.g., making girls' and boys' bodies more attractive to the other sex); shifting the circadian rhythm to allow nighttime activities (when sexual behavior tends to occur); and increasing sexual desire, novelty seeking, and emotional responsiveness. Risky behaviors that signal dominance and maturity (e.g., rule breaking, substance use) suddenly become appealing and highly valued.

Orientation toward risky behavior is more prominent in youth who follow high-risk reproductive trajectories (also called fast life history), focusing on short-term vs. long-term reproductive benefits. These youth typically come from low-resource environments characterized by poverty, conflict, parent absence, or marginalization. With few prospects to achieve reproductive status over the long-term (e.g., through high education and prestigious employment), these adolescents are more likely to engage in risky behaviors that increase their social status and short-term reproductive benefits (e.g., violence, gang activity, early sexual debut, unprotected sex, teenage childbearing). Indeed, adolescent aggression and risk taking are linked with greater mating opportunities, and the prevalence of these risky and problem behaviors is increased through peer influence processes (competition for status, peer modeling, provision of opportunities, and social norms) (Ellis et al. 2012).

Evolutionary Perspectives on Peer Relationships in Adolescence

As a transition period between childhood and adulthood, adolescence is a time when individuals enter the reproductive period of their lifespan. From an evolutionary standpoint, a crucial task of adolescence is to achieve reproductive status –

Neurobiological Bases of Peer Influence in Adolescence

The profound social-emotional and cognitive changes of adolescence reflect major brain maturation processes triggered by puberty that may have been refined through the process of evolution to maximize reproductive fitness. These

changes include synaptic proliferation and pruning, increased myelination, and stronger connectivity among brain regions. As a result, adolescents gradually improve in their cognitive control, emotion regulation, and planning skills. However, puberty also triggers the proliferation of receptors for oxytocin in subcortical neural structures, which leads to enhanced social bonding and memory for social stimuli, and together with neural changes in reward processing circuits it increases sensitivity to social stimuli. This subcortical neural maturation occurs faster than neural maturation in the prefrontal cortex, which is responsible for cognitive control and executive functioning. As a result, adolescents are highly sensitive to peer stimuli but less able to regulate their behavior, leading to greater susceptibility to peer influences compared to other developmental periods. The neural remodeling that takes place during adolescence also enhances learning potential, so peer and other experiences during this time often carry profound, life-long effects (Crone et al. 2016; Steinberg 2014).

Implications for Interventions

Many interventions targeting adolescent peer processes have been ineffective or even harmful. Such interventions fail because they attempt to change adolescent problem behavior without understanding the benefits and functions of that behavior. To be effective, interventions need to create a context where social status is earned by prosocial behaviors, while minimizing peer dynamics that confer status and other rewards for antisocial behavior. In other words, the social environment needs to be modified so that problem behaviors are no longer adaptive. For example, classroom-based behavior modification systems typically provide points or tokens for children's positive behaviors and/or remove points for negative behaviors, with the points or tokens later exchanged for valuable rewards. Similarly, anti-bullying interventions that reduce the social status benefits of bullying (e.g., through empowering bystanders to intervene and changing the attitudes of principals, teachers, students, and parents) are

more effective than those that do not address the adaptive functions of bullying (e.g., zero-tolerance policies, working with peers to resolve bullying).

The potential for negative peer influence is enhanced in settings that aggregate at-risk youth (e.g., in school, community, or criminal justice programs). When deviant adolescents are grouped together, they tend to reinforce each other's problem behavior (termed deviancy training), which leads to escalation of problem behavior over time. In addition, they can also learn new and more severe forms of antisocial behavior from each other. In these settings, high structure and careful supervision are essential to prevent negative peer dynamics of deviancy training. Additionally, it is important to integrate high-risk youth into settings with low-risk adolescents where they would be exposed to prosocial peer norms, while engaging them in positive structured activities with the low-risk youth to ensure positive peer interactions and acceptance.

Many interventions targeting adolescents focus on the dangers of risky behaviors (e.g., substance use, having sex). By advertising the costs of these behaviors, such interventions may inadvertently make risky behaviors more appealing to adolescents. More successful interventions are those that instead create positive behavioral norms (e.g., not using substances or engaging in sex) by associating these positive behaviors with images and activities that adolescents value. For example, media campaigns that linked *not smoking* with fun and social acceptance were more effective than interventions that emphasized the harmful effects of smoking on health.

Interventions also need to be sensitive to sex differences in peer status and influence. From an evolutionary perspective, men show greater variation in reproductive success than women, with more variable numbers of offspring. Additionally, females are more selective than males in choosing sexual partners. Thus, males have more to gain from high-risk behaviors to improve their attractiveness and social status, and in turn their reproductive success. Indeed, adolescent males are more likely to engage in risky behavior when in the presence of male peers of similar social status,

but such effects have not been observed in adolescent females. In summary, boys are more sensitive to social and contextual cues for status than girls. The effectiveness of peer interventions may also be affected by the ratio of boys and girls in the group and the peer status of the individual members (Ellis et al. 2012).

Conclusion

In summary, peers play a critical role in adolescence, more so than at any other time in life. With the beginning of puberty, competition for social status and reproductive success arises and intensifies during adolescence, supported by complex neurobiological maturation processes that increase sensitivity to peer stimuli and rewards while cognitive and behavioral control is still developing. As a result, the value of social status is at an all-time high and adolescents are willing to take more risks than ever to improve their standing in the peer social hierarchy. This orientation to risky behavior is especially pronounced in youth growing up in deprived, dangerous, and unpredictable environments. However, a better understanding of the evolutionary bases of peer influence in adolescence can help interventions harness the power of social status and peer norms to support more positive youth development.

[Author](#); [Neurobiologist](#); [Researcher](#)

Definition

Peggy Mason is a Professor in the neurobiology department at the University of Chicago. She received her Bachelors of Arts from Harvard University in 1983 and then continued on to earn her Ph.D. in 1987. Her early research interests examined cellular mechanisms of pain modulation. Such work in this area has focused on the role of serotonergic cells (Gao and Mason 1997; Mason et al. 2007) and pain modulation circuits in everyday life (Foo and Mason 2009).

Peggy Mason

Dr. Peggy Mason's research focus has recently switched from cellular mechanisms of pain

modulation to empathy and prosocial behavior in rats. In her current experiments, free rats are placed in an arena with a conspecific that is locked in a restrainer. Free rats are then able to open and release the restrained cage mate (Bartal et al. 2011). Dr. Mason and her colleagues found that the rats opened the cage more often when a trapped conspecific was present versus when the cage was empty or had an object in it (Bartal et al. 2011). Furthermore, the rats continued to open the cage door for trapped cage mates even when the social contact was prevented. In trials where rats had the option to open the doors for cages with chocolate or a cage mate inside, the rats would open both within minutes and share the chocolate (Bartal et al. 2011). Dr. Mason and her colleagues concluded that rats would prosocially respond to the distress of a conspecific (Bartal et al. 2011).

Dr. Mason also argues that this provides evidence for the biological roots of prosocial behavior (Bartal et al. 2014). Interestingly, while studying empathy in rats, Dr. Mason found that prosocial behavior is modulated by social experience (Bartal et al. 2014). First rats were tested to determine if they would help restrained unrelated individuals and strangers by releasing them from a cage. Results indicated that rats were willing to help both familiar cage mates and strangers, but only if the stranger was of the same strain (Bartal et al. 2014). Rats did not help strangers of a different strain. Dr. Mason and her colleagues conducted further tests where rats were housed with a rat of an unfamiliar strain for a short duration (Shan et al. 2016). After being housed with an unfamiliar strain, rats were more motivated to help that individual and release them from the restrained cage. The researchers indicated that this finding gives evidence that the social context matters when rats are choosing to help another individual or not and argue that prosocial motivation extends past the individual to group identity (Shan et al. 2016). As a final test, rats were raised with a different strain than their own from birth to determine if genetic relatedness is capable of influencing prosocial motivation. Dr. Mason and her colleagues found that when housed with a different strain, rats would not help individuals

of their own strain, but instead would act prosocially toward individuals of the strain that they were raised with (Shan et al. 2016).

Conclusion

Based on her work, Dr. Mason and colleagues have concluded that genetic relatedness is not enough to facilitate prosocial behavior. Her work provides more evidence that social context is an important factor when determining when to act prosocially toward another individual (Shan et al. 2016).

Penile-Vaginal Sex

Roy Levin

University of Sheffield, Sheffield, UK

Synonyms

Carnal knowledge; Coition; Coitus; Copulation; Fornication; Intromission; Sexual congress; Sexual intercourse

Definition

Human penile-vaginal sex occurs when the penis, usually erect, is thrust into the vagina.

Introduction

In consensual penile-vaginal sex or intercourse (PVI), where there is the agreement of both parties, the activity takes place for pleasure (recreation) or reproduction (procreation) or both, but if the female does not agree it becomes rape. Human penile-vaginal coitus with animals is usually classified as *bestiality (or zoophilia)* and is illegal in most countries. PVI or the coital act, the essential preliminary to the natural creation of another human being, has become invested for the female with attributes varying from the sacramental to psychological aspects far beyond its reproductive role. The coital act can also be used

to express motives as diverse as “to degrade, to punish and hurt, to overcome loneliness and boredom, to rebel against authority, to establish one’s sexuality, or one’s achieving sexual competence (adulthood), or to show that sexual access was possible (‘to score’), for duty, for adventure, to obtain favours such as a better position or role in life, or even for a livelihood” (Levin 1994).

Activating the Vagina for Coitus

The vagina is a potential space with a W or H cross-section, usually the anterior (upper) and posterior (lower) walls are collapsed. To prevent adhesions, their surfaces are kept just moist by transudation of a plasma filtrate from their capillary blood supply. The latter is under local control called “vasomotion” where only the minimum number of capillaries are kept open at anyone time to maintain the organ’s viability (Levin and Wiley 2008). This, however, does not allow pain-free penile penetration so sexual arousal increases the vaginal blood flow by neurally releasing the vasodilator neurotransmitter VIP (vasoactive intestinal peptide) and reducing the activity of its sympathetic innervation vasoconstriction of the blood vessels caused by noradrenaline. This alters the restriction on the vaginal microcirculation opening up the closed capillaries by reducing vasomotion. The increased capillary area and vasocongestion creates enhanced transudation of the plasma ultrafiltrate and greatly increases the lubrication of the surfaces facilitating penile penetration and thrusting. In the Western world, such enhanced lubrication is highly regarded as an index of successful female arousal but in a number of African states men prefer a dry, tight vagina for coitus influencing women to use methods of drying up their genital fluids.

During coitus, the male receives sexual pleasure from the friction generated by the thrusting of the penile glans (head) and shaft against the walls of the vagina and the vaginal entrance (introitus) and its surrounds (vestibule). The female’s pleasure comes from the dynamic friction and pressure of the thrusting penis against a number of genital structures containing various sensory end

organs innervated by the hypogastric nerve (uterus and cervix), the pelvic nerve (vagina and cervix), and the pudendal nerve (the clitoris). These genital structures can include the glans (head) of the clitoris, the introitus and the area of the vestibule around the urethral opening (periurethral glans), Halban's fascia (the vaginal/bladder septum), the vaginal walls especially the anterior (upper) with its inclusions of the urethra, internal aspects of the clitoris (crus and vestibular bulbs), and controversial G-Spot and, in a few women, the cervix (Levin 2015) but see the section on the cervix. Thus, for the female, PVI is a multisite stimulus and should excite the female rapidly and strongly, but in actuality most females find that stimulation of the clitoral glans brings about sexual arousal and orgasm more quickly and often with stronger force although not always as satisfying as that from coitus. The multisite nature of PVI creates difficulties for women's self-reporting of where the erotic stimulus comes from to create arousal to orgasm (Levin 2015). If the female is receptive and sensitive to the PVI it can lead to initiating the female orgasm per se, but this does not occur in all women many of whom need additional clitoral stimulation even during PVI to achieve orgasm (Levin 2014).

The Female Orgasm Problem

Freud (1905) suggested from his psychoanalytical work with female Austrian patients that "the development of female sexuality is complicated by the fact that the girl has the task of giving up what was originally her leading genital zone- the clitoris – in favor of a new zone – the vagina" and "if the clitoral zone refuses to abandon its excitability the young woman can become anesthetic at the vaginal orifice." This opinion later became transmuted by other Freudian psychoanalysts into the concept of a "clitoral orgasm" and a "vaginal orgasm" (attained from PVI alone) and that the "clitoris undermined healthy femininity." It was suggested that "investment in the clitoris is a barrier to the development of an adult femininity." While these concepts became outdated with the rise of feminism and

biologically based psychiatry recent ardent supporters of this "undermining healthy femininity" concept are Brody (2010) and a small coterie of co-workers who claim that clitoral stimulation in women leading to orgasm is not beneficial to their physical, psychological, interpersonal, or behavioral health and that only PVI with its induced orgasm (without clitoral stimulation) are able to create and maintain "normality" of the psychological and physical health of women. A major proposal of Brody (2010) is that PVI and its orgasm is the "one potentially reproductive sexual behavior" so that evolution "rewards" it while other sexual activities (fellatio, clitoral stimulation, masturbation, cunnilingus) are "punished" and lead to "noxious outcomes." Such an explanation is highly simplistic because any human sexual activity can always lead to the possibility of PVI thus no need to "punish" it. This stance of "demonizing the clitoris and sanctifying the vagina" has been extensively criticized (Levin 2014, 2015; Prause 2012; Laan and Rellini 2011).

The Anterior Vaginal Wall Complex

As mentioned previously, the anterior vaginal wall is the site for a number of structures that when stimulated generate erotic arousal (Levin 2015). The female urethra, running from the bladder exit to the urinary meatus (opening), is a short muscular tube containing a lining epithelium scattered with paracrine cells that secrete 5- hydroxytryptamine (serotonin) on activation. It is released from the stretching of the urethra by penile thrusting of the vaginal wall and sensitizes local nerves so facilitates turning the urinary conduit into an active sexual organ. Halban's fascia contains pressure sensitive end organs that also transmit impulses that activate arousal during coitus. The G-spot is a proposed structure that when stimulated by pressure activates sexual arousal. It has been the focus of a number of studies that have tried to identify it by a variety of techniques namely ultrasound, anatomical dissection, and most recently MRI. Unfortunately, some of the studies have identified structures that are different in size and position but none

have shown definitively that they are the functional G-spot (Levin 2015).

Is the Cervix Stimulated in PVI Causing Sexual Arousal?

Some misleading reports suggest that the cervix is stimulated by penile buffeting during PVI creating sexual arousal and even orgasm. These reports are not stringent in that they do not take into account a number of important factors, viz. (i) that when women are actively sexually aroused their utero-cervix complex is withdrawn up away from the penile thrusting axis (vaginal tenting) by striated and smooth muscle contractions into the false pelvis (Masters and Johnson 1966). It has been confirmed by direct observation, genital imaging (MRI), and electrical recording (Levin 2015). This expansion of the upper vagina gives many women during PVI the sensation that the “penis is lost in the vagina” (Masters and Johnson 1966), (ii) the sensory innervation of the cervix is so poor that some minor surgery can be accomplished without anesthesia (Levin 2015), (iii) anatomical and physiological conditions inhibiting vaginal tenting (obstetrical trauma from childbirth, especially long cervices, uterine prolapse), and (iv) poor sexual arousal leading to inadequate vaginal tenting.

Conclusion

Despite many studies of penile-vaginal sex in humans, there are still important functional issues that remain controversial and contentious; a number of these have been described in this entry. More stringent investigations and analyses are needed.

People's Responses to Personal Ads

Tobias Otterbring
Aarhus University, Aarhus, Denmark

Synonyms

[Ad exposure](#); [Advertising effects](#); [Marketing influences](#)

Definition

The way people are influenced by advertisements appearing in magazines, newspapers, and other visual media outlets.

Introduction

Humans and human-like stimuli are used extremely frequently in advertising, given their ability to attract attention better than almost any other stimuli. As consumers, we are exposed to a wide array of marketing messages every day, many of which are shown to us visually through pictures or commercials featuring other humans. One group of humans that is hugely over-represented in advertising, and whose presence is presumed to produce profit, is aesthetically appealing and attractive humans. Pictures of such “hot” humans are often used with the implicit assumption that they will benefit the advertised products or brands through the beauty and sex appeal they convey. Even though meta-analytical research shows that sex does not sell particularly well in advertising (Lull and Bushman 2015), many companies still use sex cues and physically attractive individuals in their marketing campaigns. Recent studies also suggest that such “sexy” stimuli can have an impact on consumers’ financial decisions under certain circumstances.

Sex Sells Sometimes

Several studies have shown that appetitive stimuli, such as physically attractive individuals or sexually laden objects, exhibit cross-domain effects on impatient and impulsive responses, resulting in a generalized change in time preferences toward present pleasures and vices over virtues (e.g., Chiou et al. 2015; Otterbring and Sela 2017; Van den Bergh et al. 2008; Wilson and Daly 2004). In a classic study by Wilson and Daly (2004), participants were exposed to either “hot” or “not” stimuli (attractive vs. unattractive opposite-sex faces). After indicating how appealing they found the stimuli, participants were asked to choose between smaller-sooner and larger-later monetary rewards, for example, whether to receive \$15 tomorrow or \$50 in a week. Participants exposed to the “hot” stimuli were significantly more likely to favor the smaller-sooner monetary rewards; this effect was especially apparent among men, consistent with the view

that men tend to value a potential mate’s physical attractiveness more than women (Saad 2004).

Van den Bergh et al. (2008) exposed men to commercials with sexually laden (vs. neutral) content and examined whether type of exposure would influence participants’ financial decisions. Men in the sex-cue condition were shown physically attractive and alluringly dressed women, whereas men in the control condition were shown neutral stimuli. Mirroring the findings by Wilson and Daly (2004), men in the sex-cue (vs. control) condition were more inclined to choose smaller-sooner over larger-later monetary rewards. However, such sexy stimuli not only impaired men’s ability to make mature financial decisions. In a subsequent study, Van den Bergh et al. (2008) generalized their findings beyond the financial domain by showing that men who touched bikinis (vs. t-shirts) were more likely to prefer receiving fewer candy bars and soft drinks instantly instead of a larger number of these items at a later point in time. More recent research also shows that regardless of whether men are touching or only viewing sexually laden objects (such as lingerie), such stimuli make them willing to pay more for rewarding foods and beverages compared to if they are exposed to neutral stimuli (such as shirts) that lack a clear connection with sex (Festjens et al. 2014). Similarly, pictorial exposure to attractive (vs. less attractive) women makes male smokers significantly less likely to refrain from smoking during survey completion, with a more present-oriented mindset mediating this effect (Chiou et al. 2015).

Because both hunger and sexual desire have been shown to impair individuals’ ability to refrain from acting on impulse (e.g., Chiou et al. 2015; Orquin and Kurzban 2016), thereby shifting their preferences toward instant gratification and short-term goals, Otterbring and Sela (2017) examined the interactive effect of these drive states in an advertising context. Participating men and women were assigned to one of three advertisement conditions: neutral ads, sexy ads, or no ads. Participants in the neutral ads condition were shown six ads featuring nature motives, participants in the sexy ads condition were shown six ads with sexual content, and participants in the

control condition did not see any ads. Framed as a second part of the study, participants were presented with a series of binary choices between smaller-sooner and larger-later monetary rewards, after which they indicated their hunger. The results revealed that exposure to sexy (vs. neutral or no) ads made men significantly more financially impatient than women. This finding may be explained by the fact that men are more easily aroused by visual sexual stimuli than women and tend to have more positive attitudes towards explicit depictions of sex in advertising (e.g., Sengupta and Dahl 2008). However, hunger further moderated this effect, which only influenced hungry (vs. satiated) individuals: Hungry men made significantly more short-sighted financial decisions after viewing sexy (vs. neutral or no) ads, whereas women made significantly more future-focused monetary choices after similar exposure. Hence, the simultaneous activation of several distinct drive states seems to have interesting interactive effects on people's financial decisions, with sexual desire exerting a particularly powerful influence on monetary choices when another drive state is salient at the same time.

Apart from the above-stated findings, all of which focused on mate attraction motives or stimuli meant to induce a mating mindset, research also shows that mate competition motives (such as encountering a challenging same-sex rival) can influence people's purchase behavior.

Same-Sex Stimuli May also Sell

In a series of studies, Otterbring et al. (in press) examined how exposure to physically fit men, such as muscular male models featured in advertisements or the "handsome hunks" who work at stores like Abercrombie & Fitch, would influence male and female consumers' consumption patterns. Contrary to consumer lay beliefs, a field study demonstrated that the presence (vs. absence) of an athletic-looking male employee at the main entrance of a retail store made male consumers spend significantly more money than female consumers. However, this effect was not merely due to male consumers

purchasing a larger number of products than their female counterparts. Rather, the effect was driven by male consumers purchasing substantially more expensive products in the presence of the physically fit male employee, presumably in an attempt to signal status when encountering such an imposing same-sex rival, as status displays have resulted in reproductive success for men. Supporting such a status-signaling account, men and women in another related study were exposed to either a muscular or a nonmuscular male advertising model. After replying to a set of items related to the model, participants were presented with a blank shirt and asked to draw a brand logo on the shirt in a size they would prefer if they would buy the shirt themselves. Interestingly, whereas women's logo size drawings were not influenced by type of exposure, men exposed to the muscular (vs. nonmuscular) male model drew significantly larger logos, in line with the claim that status can be signaled through both price and size. Furthermore, consistent with the so-called Napoleon complex, this effect was even stronger among those men who lacked a bodily marker of dominance themselves (i.e., men with shorter stature or height). In yet another study, Otterbring et al. (in press) again exposed men and women to a muscular (vs. nonmuscular) male model, after which participants were asked to indicate how much money they were willing to spend on various products. Some products were strongly linked to status (such as a new car, jewelry), whereas others were not (e.g., household goods like batteries and light bulbs, or snacks). Similar to the findings on logo size drawings, women's willingness to spend money did not differ across conditions; however, men exposed to the muscular (vs. nonmuscular) male model were more motivated to spend money on the status-signaling products; this effect was again moderated by the men's own level of physical dominance, this time measured through the 2D:4D digit ratio. Thus, men with higher digit ratios (indicating lower levels of testosterone) were most likely to engage in status-signaling consumption after exposure to a muscular male advertising model, and their elevated feelings of intrasexual competitiveness drove this effect.

Conclusion

Consumers' decision making can be influenced by advertisements, commercials, and other marketing messages featuring sexually laden stimuli. Exposure to such stimuli typically results in more short-sighted decisions in men, but has weaker effects in women, and sometimes even evokes more future-focused female responses. Apart from advertising that aims to produce profits through mate attraction cues, recent research also suggests that mate competition cues can drive the dollars in the desired direction, as long as the products to be purchased signal status through price or size.

Perceived Control and Suicide from an Evolutionary Mismatch Perspective

Synonyms

[Appraised helplessness and self-slaughter](#); [Perceived insurmountable problems and self-murder](#); [Sense of powerlessness/helplessness and self-destruction](#)

Definition

Individuals are at a greater risk of killing themselves when they have developed a sense of

powerlessness in relation to dealing with certain overwhelming problems in their lives. Such a drastic action, generally induced by one's judgment that he/she is incapable of influencing an outcome of vital importance, is believed to have been adaptive in some situations for the majority of prehistory from an evolutionary perspective. However, as a result of considerable familial/social transformations in the modern environment in comparison to the ancestral context, attempts at self-murder are conceived to be much less likely to serve any useful evolutionary function in the present day.

Introduction

Perceived control, the notion people hold regarding their ability to be in charge of their personal emotions/thoughts/actions and/or living conditions in engendering preferred consequences, has long been implicated as one of the core cognitive factors that could shape a person's well-being (Wallston et al. 1987). The worst possible impact perceived control (or the lack thereof) could have on one's welfare though pertains to its relationship with suicide – the act of terminating one's own existence. A vast body of empirical research has proffered the critical role a self-appraisal that one is incapable of influencing the outcomes of significant existential challenges can play in effecting suicidal acts (e.g., Gibbs et al. 2009). However, while the suggestion that a sense of powerlessness in dictating certain life events is instrumental in heightening one's suicide risk appears reasonable from the standpoint of logic, the idea that individuals would engage in self-murder in the wake of a perceived lack of control seems baffling from an evolutionary perspective (in which a continued existence is posited to be the primary objective of all living organisms) on the face of it (Nedelcu et al. 2011). What evolutionary function would self-destruction confer on an individual who has perceived that his/her problems are insurmountably beyond his/her control?

Evolutionary Underpinnings of Perceived Control-Suicide Link

Researchers have probed more deeply into this puzzle over the last few decades, and two persuasive explanations have arguably stood out from the rest to this end. One of them is deCatanzaro's (1980, 1991) inclusive fitness formulation. According to this approach, an individual could be at risk to kill oneself if he/she determines that his/her enduring survival might be detrimental to the evolutionary fitness of his/her biological relatives (deCatanzaro 1991). A terminally ill person, in this regard, would supposedly enhance his/her biological relatives' fitness through suicide by freeing up resources that would otherwise be directed to himself/herself if one has continued to exist (deCatanzaro 1991). Another prominent school of thought alternatively contends that an attempt at self-destruction is instead actually an intense cry for help to those who might stand to benefit evolutionarily from one's survival (e.g., Watson and Andrews 2002). Such a dangerous endeavor is believed to be necessary in order to elicit vital assistance/resources from close ones so as to resolve one's difficulties (Watson and Andrews 2002). A large proportion of empirical evidence to date has largely endorsed the cry for help formulation over that of the inclusive fitness approach (Syme et al. 2016). Regardless of the relative strength of their empirical validity however, a common thread that underlies both formulations is the assumption that one would initially perceive a lack of control in modifying his/her adverse situation which could in turn play a role in his/her eventual decision to attempt self-destruction (deCatanzaro 1981; Syme et al. 2016). Although such an undertaking might serve an adaptive function in the ancestral era, it might nonetheless be evolutionarily counterproductive in the present context.

Perceived Control-Suicide Link from an Evolutionary Mismatch Viewpoint

For instance, it is logical to assume that engaging in self-destruction might have enhanced one's

inclusive fitness (e.g., the fitness of one's kin) especially if the individual was faced with a perceived uncontrollable threat (e.g., being partially paralyzed from an accident), which might have required much attention and resources from kin for his/her continued survival in the prehistoric context (where one would generally reside together with kin in a closely knitted band) (Buss 2000). Such an extreme evolved strategy to enhance one's inclusive fitness in the present environment might be much less adaptive though in the evolutionarily novel present context, given that most people currently no longer reside in close proximity to their biological relatives (and hence would not have posed as much of a burden to them) (Buss 2000). By the same token, trying to obtain help from one's biological relatives by engaging in the potentially prehistorically adaptive dangerous strategy of attempted suicide when one has encountered a perceived uncontrollable threat could likewise be evolutionarily counter-productive in the modern environment – one's kin might not be physically close enough to render much-needed assistance and hence one could run the risk of actually completing the act (e.g., die) without obtaining the desired assistance on time. Furthermore, the provision of “social welfare” in an abundant of nations around the world in the present day has rendered self-destruction attempts evolutionarily superfluous, because such societal support has significantly alleviated the strain on family members and has widely broaden the options for help-seeking for those who might be in distress (Aubin et al. 2013, p. 6881).

Conclusion

In sum, the act of killing oneself, purportedly driven by a lack of a sense of control over one's negative circumstances in life, could conceivably have served some evolutionary functions in the ancestral period. In light of the considerable changes in the societal/familial make-up in the modern world (in juxtaposition to the prehistoric context) however, such an extreme stress-coping strategy is believed to be evolutionarily non-adaptive on the whole in the current environment.

Definition

The phenomenon of perceiving another's behavior as sexual.

Introduction

In any one day, our activities often involve some sort of signaling to other individuals within our environment. Interactions with coworkers, friends, family members, partners, and even random strangers are a typical daily occurrence, yet the complexity of human interactions often leaves room for ambiguity. When it comes to interacting with potential mates, the ambiguity widens, sometimes resulting in the misinterpretation of signals between two individuals. A signal can be linguistic in nature, but it can also rest in body movement or a gesture at just the appropriate time. A smile and a touch on the leg can mean two very different things depending on the context. As humans, we have evolved behaviors to help us navigate the ambiguity of our complex behavioral signaling, but we will never be able to perfect a system by any means.

Error Management Theory and the Overperception Bias

Error management theory (EMT) is the idea that a bias should evolve due to an asymmetry in cost: the cost of a false positive versus a false negative (Haselton and Buss 2000). When in uncertain situations, the possibility of two errors exists: false positives (Type I errors), and false negatives (Type II errors). A Type I error is also sometimes referred to as a “false alarm” and a Type II error a “missed detection.” In a mating relevant context, a missed detection would be considered more costly than a false alarm due to the potential loss of a romantic partner. Sexual overperception bias is a solid example. Due to different selection pressures, especially the asymmetrical nature of Parental Investment (Trivers 1972), the overperception bias evolved via Error Management Theory. This can be understood in terms of costs versus benefits, where the costs of missing a sexual opportunity outweigh the costs of lost time. It is important to mention that this only applies to the sex with lower reproductive investment (males typify this category, but in some species this is not the case). If males regularly miss out on opportunities, they will be out-reproduced by other males that took opportunities. On the other hand, females face constraints due to reproductive efforts (i.e., gestation and offspring care) (Trivers 1972). Many research studies have found evidence in support of men over-perceiving women's sexual intent, supporting the idea that the asymmetrical nature of Parental Investment drives error management, resulting in the overperception bias in males. Of course, there is much research needed on the mediating factors of the overperception bias. For instance, though males do tend to over-perceive female's sexual intent, sociosexuality is a strong predictor of both men and women interpreting flirtatiousness.

The Influence of Alcohol on Overperception

Other factors can play into the overperception bias as well – especially situational factors. For

instance, alcohol use by a man or woman can greatly increase the overperception bias. At singles mixers, alcohol is almost always a must and is often used as an icebreaker when meeting potential partners. On the reality show, *The Millionaire Matchmaker*, the main character has a set of rules that all her potential clients must follow. One of the number one rules that is often broken is a limit on alcohol consumption when going on dates with one another. By sticking to a “two-drink maximum rule,” individuals avoid potentially embarrassing themselves. Simply put: The over consumption of alcohol leads to the overperception of sexual intent.

Conclusion

Human interactions can often be complex, but when considering the perception of sexual intent, a multitude of other variables come into play. Specifically, environmental factors and the individual’s sex play prominent roles when perceiving sexual intent from an individual. That being said, there are many questions left open-ended and unanswered before we can begin to fully understand the true nature behind the perception of sexual intent.

Definition

People’s attitudes toward different behaviors or information about their romantic partner that may constitute infidelity.

Perceptions of Infidelity

Researchers have come to the conclusion that there are two distinct forms of infidelity: sexual and emotional infidelity (Shackelford and Buss 1997). While sexual infidelity is considered as engaging in sexual behaviors (i.e., penile-vaginal intercourse, oral sex) with someone other than your primary partner, emotional infidelity refers to forming an emotional and intimate bond with someone else. However, despite this distinction, there is not much agreement on how to define infidelity and which behaviors might be perceived as a sign of sexual or emotional infidelity. The

same behavior might be sometimes considered as infidelity and sometimes not. A qualitative study states that even experienced couple counselors who worked with couples experiencing infidelity have conflicting definitions of infidelity (Moller and Vossler 2015). A descriptive study demonstrates that what people consider as infidelity varies based on their gender, attachment avoidance, and attachment anxiety (Kruger et al. 2013). Specifically, women gave higher ratings than men to several behaviors. Moreover, people high in attachment anxiety were more likely to consider many behaviors as infidelity, whereas attachment avoidance was related to decreases in the rating of behaviors as infidelity. Overall, sexual behaviors were rated as the most defining behavior of infidelity.

A seminal evolutionary psychology study showed major sex differences in response to different types of partner infidelity (Buss et al. 1992). Specifically, when participants were asked to choose which type of infidelity would make them more distressed (e.g., sad, jealous), males selected sexual infidelity as the most distressing type of infidelity, whereas it was emotional infidelity for women. Buss and his colleagues (1992) claim that men and women experience different reproductive challenges when their partners engage in different types of infidelity. For instance, men might experience paternity uncertainty when their partner engages in sexual infidelity, whereas women might lose their resources when their partner engages in emotional infidelity. Despite several replications of this hypothesized evolutionary sex difference, some researchers question the validity of this finding. For example, when a continuous scale was used instead of the previously used forced-choice question, no sex differences in response to partner infidelity were identified (DeSteno and Salovey 1996). Similarly, another study didn't also find this sex difference and showed that both men and women were more distressful in face of sexual infidelity as compared to emotional infidelity (Brogdon et al. 2006).

In another study, whether perceptions of infidelity could change based on the sex of the judge and the sex of the target individual, who was judged in terms of whether they engaged in infidelity or not, was investigated (Hackathorn and

Harvey 2011). Interestingly, they found that women were more likely to perceive infidelity when the target was a man, and similarly, men were more likely to perceive infidelity when the target was a woman. A factor that could contribute to this finding is same-sex protection, meaning that people might more easily empathize with members of their own sex, whereas they might become defensive when infidelity behaviors are enacted by the opposite sex.

Given the detrimental impacts of infidelity on individuals, it is important to be able to detect partner infidelity. From an evolutionary perspective, infidelity might be even considered as an adaptive mechanism since it gives the individual the chance to reevaluate their current relationship and even find a better mate after detecting partner infidelity. The literature suggests that it is possible to detect the presence of infidelity based on brief observations. For instance, researchers demonstrate that just seeing 3–4 min “thin slices” of couple interaction was enough for observers to accurately identify people who had cheated on their partners (Lambert et al. 2014). They also found that trustworthiness and commitment were two variables that mediate the relation between observers' ratings and targets' actual infidelity behaviors. Therefore, first impressions of trustworthiness might be one possible way to detect infidelity. Voice pitch is another factor that influences people's perceptions of infidelity (O'Connor et al. 2011). Specifically, men, but not women, are more likely to attribute infidelity to feminized women's voices (i.e., higher pitch). On the other hand, women, but not men, are more likely to attribute infidelity to masculinized men's voices (i.e., lower pitch). Moreover, another study showed that people accurately judged an unfamiliar target's past faithfulness from their voice (Hughes and Harrison 2017). Specifically, judges rated people who actually had cheated on their partners as more like to cheat after controlling for voice attractiveness and pitch.

Conclusion

While it is somewhat ambiguous how common infidelity is defined these days, research suggests

that its prevalence is somewhere between 1.2% and 85.5%, and this reported frequency depends on the way people define it and the sampling methods studies use (Moller and Vossler 2015). Despite this ongoing debate, there is no doubt that infidelity poses threats to both relationship and individuals, such as paternity uncertainty, divorce, or even abuse. Therefore, it is important to deter partner infidelity to decrease stress due to uncertainty and have long-lasting and satisfied relationship.

Perceptions of Infidelity Cues

Jillian J. M. O'Connor
Department of Psychology, Concordia University,
Montreal, QC, Canada

Synonyms

[Assessing faithfulness](#); [Detecting romantic cheating](#)

Definition

The assessment of visual or auditory information in relation to a potential mate's future likelihood of sexual unfaithfulness.

Introduction

Both men and women are vulnerable to the fitness risks of selecting an unfaithful long-term mate. Owing to this selection pressure, individuals who perceive and attend to infidelity cues during mate search may be better able to avoid the potential fitness costs of cuckoldry from unfaithful female mates, or reduced investment and protection from unfaithful male mates. Cues to infidelity stem from hormonally dependent traits, such as the degree of facial and vocal sexual dimorphism (male masculinity, female femininity). These cues contribute to perceptions of infidelity independently of their attractiveness and also have implications for mate selection.

Male Masculinity

Research suggests that women use markers of underlying testosterone to assess the risk of male infidelity. Relatively high levels of testosterone are necessary for the development of masculine male facial features, such as a broad jaw and prominent brow ridge (for review see [Feinberg 2008](#)). Similarly, the development of a lower-pitched voice (aka vocal masculinity) is dependent upon pubertal levels of testosterone (for review see [Feinberg 2008](#)). Among men, both vocal and facial masculinity vary with individual differences in levels of testosterone, and both traits have an influence on perceptions of infidelity.

In two separate studies, women listened to men's voices which were artificially manipulated to be higher or lower in pitch and were asked to select who was more likely to cheat on their romantic partner ([O'Connor et al. 2011, 2014](#)). Women were significantly more likely to select the lower-pitched male voice as presenting a greater risk of infidelity. Similarly, when asked to rate the likelihood of infidelity from men's faces which had been manipulated to appear more masculine or feminine, women rated masculinized male faces as more likely to cheat than feminized men's faces ([Kruger 2006](#)). When taken together, these studies demonstrate that women associate infidelity risk with the expression of testosterone both in men's voices and faces.

Male facial masculinity also has an important role in the accuracy of perceptions of infidelity risk. [Rhodes et al. \(2013\)](#) recorded men's history of infidelity and photographed their faces. Female participants then rated the likelihood of infidelity from photographs of the men's faces. Women were able to accurately assess the risk of infidelity from facial photographs alone, but only when viewing masculine men's faces. This suggests that perceptual associations between masculinity and infidelity risk have a role in women's ability to discriminate between faithful and unfaithful potential mates.

Women may perceive testosterone-dependent traits as associated with an increased risk of

infidelity owing to associations with unfaithful behavior. Among men, higher levels of testosterone are associated with higher reported rates of infidelity ([Booth and Dabbs 1993](#)). Men who possess other masculine, testosterone-dependent, traits, such as broad shoulders relative to narrow hips, also report a higher frequency of infidelity ([Hughes and Gallup 2003](#)). Therefore, men with relatively high testosterone are likely to possess masculine faces and voices, as well as engage in extra-pair sex, and are more likely to be perceived as romantic cheaters.

Female Femininity

Among women, relatively feminine facial and vocal traits influence perceptions of infidelity risk. Feminine women's faces are characterized by a small jaw and large eyes, whereas feminine women's voices are higher in pitch. Both vocal and facial femininity are associated with relatively higher levels of estrogen (for review see [Feinberg 2008](#)) and also have similar influences on perceptions of infidelity. Men perceive women with higher-pitched voices as presenting a greater risk of infidelity than women with lower-pitched voices ([O'Connor et al. 2011](#)). In comparison to masculine-looking women's faces, men perceive feminine-looking faces as more likely to be unfaithful ([Rhodes et al. 2013](#)). However, men appear to be unable to accurately assess the risk of infidelity from individual women's faces, regardless of the degree of facial sexual dimorphism ([Rhodes et al. 2013](#)).

Men's perceptions of increased infidelity risk from women possessing feminine traits may be owing to associations between estrogen levels and individual differences in the propensity for infidelity. Women with higher levels of estrogen report a greater future likelihood of adulterous behaviors ([Durante and Li 2009](#)). Women who possess other estrogen-dependent traits, such as wider hips and a smaller waist, also report higher rates of extra-pair sex ([Hughes and Gallup 2003](#)). This suggests that men's perceptions of increased infidelity risk from feminine women's faces and voices could be based on a kernel of truth.

The Role of Attractiveness in Perceptions of Infidelity

When examining perceptions of infidelity from sexually dimorphic faces and voices, the attractiveness of such traits could contribute to perceived infidelity risk. It is possible that female femininity and male masculinity are perceived as presenting a greater risk of infidelity because of differential sexual opportunity among attractive individuals. Furthermore, physical attractiveness in general has been linked with perceptions of infidelity risk (Rhodes et al. 2013; Waynforth 2001). Indeed, individuals with more attractive voices report higher rates of infidelity (Hughes et al. 2004). In order to examine this possibility, O'Connor et al. (2011) tested listener's perceptions of both infidelity and attractiveness. The results indicated that vocal attractiveness ratings were unrelated to perceptions of infidelity. In addition, Rhodes et al. (2013) found that men's facial attractiveness was not related to either women's perceptions of infidelity or the accuracy of their perceptions. Therefore, sexually dimorphic faces and voices function as a cue to infidelity risk, over and above any potential contributions of attractiveness.

Implications for Mate Choice

Given that the same traits that influence perceptions of infidelity also influence perceptions of attractiveness, it is important to consider the potential implications for mate choice. Both men and women value fidelity in a potential long-term mate, and disregarding cues to infidelity risk could increase the probability of future infidelity-related fitness costs. Consequently, cues to infidelity are likely to have a greater impact on mate preferences in the context of a long-term relationship. For instance, the more women attributed infidelity to lower-pitched voices, the weaker their preferences were for lower male voices for long-term versus short-term relationships (O'Connor et al. 2014). Thus, perceptions of infidelity risk from men's voices may function as an adaptive heuristic that helps

women avoid the potential fitness costs that could result from infidelity, such as the loss of resources and protection, yet allows the potential for women to obtain genetic benefits from short-term mating with high-testosterone males.

Conclusion

Facial and vocal sexual dimorphism provides a rich source of information when assessing potential mates for the probability of future infidelity. The influence of facial appearance and voice pitch on perceptions of infidelity is consistent with the associations between extra-pair behavior and the hormones underlying these traits. Individuals who attend to such cues may be better able to avoid the potential fitness costs stemming from partner infidelity.

Permissibility of Reproduction

Anna Wysocki
Oakland University, Rochester, MI, USA

Synonyms

[Antinatalism](#); [Natalism](#)

Definitions

The permissibility of reproduction refers to the debate over the morality and ethics of reproducing.

Introduction

Having a child is one of the most significant decisions a person can make within their lifetime. This decision has the potential to impact not only the parents but also the child and society at large. However, it is considered by some to be one of the most rewarding decisions that a person can make. Regardless, it is a decision that requires consideration of financial, physical, and emotional readiness. Much of the debate surrounding the ethics of procreation is centered around discussing the situations wherein procreation may or may not be

permissible. For example, if during pregnancy parents find out their child will have a debilitating congenital disease, would it be ethical to bring that child into the world knowing that it may not have a good quality of life? Natalists agree that there are situations, perhaps even most situations, wherein procreation is ethical. However, there is disagreement about the precise factors that may lead to procreation being unethical. Additionally, there is another academic group – the antinatalists – who also contribute to the debate on the ethics of procreation. The antinatalists assert that procreation is impermissible and, therefore, there are no situations wherein it may be ethical to procreate.

The Natalist Debate

Between natalists, there are some who find simply questioning the ethics of procreation to be offensive (Anscombe 1989). Others believe that, considering the personal nature of the decision, procreation cannot be subject to ethical debates or moral duty (Little 1999). However, many natalists concede that, given the high consequences, procreation does need a defense (DeGrazia 2012). There is disagreement towards how strong this defense must be. Some believe that it is sufficient for prospective parents to simply want to provide a good life for their child, whereas others believe that desire is insufficient and that there must be a reasonable expectation that the parents' will be able to provide the child with a good quality of life (e.g., financial stability). Still others believe that reasonable expectation is insufficient and it is necessary to select for children that have the best chance of a good life (i.e., genetic screening; Douglas and Devolder 2013; for further discussion on the natalist debates, see Hannan et al. 2015).

The Antinatalist Debate

Different versions of antinatalism have been proposed and defended based on different assumptions. For example, it has been proposed that procreation is unethical because of the lack of

consent from the child being brought into the world (Shiffrin 1999). Throughout an individual's life, he or she will experience a vast amount of pain and suffering, which arguable no one – not even a parent – has the moral right to force upon another without the person of interest's consent. Since consent cannot be attained prior to conception, procreation is thus never permissible (Shiffrin 1999). Others have argued that the worst outcome imaginable for an individual vastly outweighs the best outcome possible (Hayry 2004). This perspective contends that because it is impossible to know before procreation whether a child will have a good or a bad life, it is not morally permissible to bring a child into a world wherein they have a chance of their life having the worst outcome possible (Hayry 2004).

Another argument for antinatalism is that the suffering of sentient beings should always be avoided. Antinatalists extend this principle to state that there is harm in coming into existence and this harm greatly outweighs the benefits of existence. The asymmetry argument, proposed by David Benatar, a lead advocate of antinatalism, states that when coming into existence there are harms (–) and benefits (+) associated with existence. Alternatively, there is an absence of harm (+) and an absence of benefits (neutral) associated with nonexistence. Herein lays the asymmetry: whereas the harm (–) and benefit (+) may neutralize each other, the absence of harm (+) and the absence of benefit (neutral) results in a net positive for nonexistence (for a more detailed explanation and discussion of the asymmetry argument, see Benatar 2006).

Natalists often have one of two responses to the asymmetry argument. First, that suffering is not necessarily bad (e.g., Benatar and Wasserman 2015). They contend that suffering is what allows humans to appreciate the benefit, and that suffering can result in growth and actually improve life satisfaction and quality of life in the long term. The second response has to do with the asymmetry argument, whereby many natalists disagree with a fundamental tenant of the argument (see Smuts 2014). Specifically, natalists believe that the harm (–) and benefit (+) of coming into existence do not necessarily neutralize each other, nor do they believe that the harm (–) outweighs the benefit

(+). Rather, they contend that, in many cases, the benefit of existence far outweighs the harm. To support this claim, they point to the many joys of life (e.g., food, friends, and positive experiences) as well as self-reports from people. The vast majority of people, if asked, would report that their life contains more good than bad, and that they are happy to exist. How then, natalists ask, does the belief that one's life has more harm than benefit remain (Benatar and Wasserman 2015)?

The response from antinatalists originates from a phenomena discovered by psychological research called *the optimism bias*. The optimism bias describes the tendency for humans to believe their life is significantly better than it actually is. For example, researchers found that after a major accident that resulted in a loss of a limb or paralysis, participants had a decrease in perceived quality of life. However, within months, participants' reports of quality of life were back at their baseline without a significant change in their life circumstances. Furthermore, antinatalists point to the many harms and discomforts of life that are overlooked because they are shared among every human. These include hunger, thirst, exhaustion, and stress. Although it may seem unusual to count these as harms, Benatar asks his readers to imagine an alien species that never had any of these human harms. If this species were to come into contact with humans, would they view these daily annoyances as harm? Benatar contends that simply because a harm is shared by all members of a species does not make it less of a harm (Benatar and Wasserman 2015).

Conclusion

The debate over the permissibility of procreation is on an unorthodox topic that many believe should not even be subject to discussion. As outlined above, there is disagreement concerning not only the situations in which procreation is unethical but also whether there are any instances where procreation is ethical. Regardless of these differing theories, there is a general agreement between academics debating procreation that this is a topic that deserves careful and thoughtful consideration.

Perpetrators Mostly men

Raquel Oliveira

[Male aggression](#); [Male offenders](#); [Male violence](#);
[Males and crime](#)

Definition

Most crime, especially violent crime, is committed by males, which might be explained by mating efforts as well as exposure to specific androgens.

Introduction

It has been widely shown that males commit more crime than females and that males commit more violent crime than females. Several criminological explanations have been proposed as to why this happens. Evolutionary psychology provides a unique insight into human behavior that considers biological and genetic aspects, derived from the evolution of the species, that remain relevant and essential in the explanation of all human behavior, including criminal behavior.

Gender Differences in Criminal Involvement: Why are Perpetrators Mostly men?

Research has widely shown that males offend more and more violently than females, being that this relationship seems to hold for most crimes (except prostitution) and across different locations (Farrington and Painter 2004; Lancot and LeBlanc 2002; Moffitt et al. 2001).

According to Darwin, aggression, such as any other trait, exists to ensure survival. From an evolutionary standpoint, individuals had to fight for resources, survival, and mating opportunities, being that those who were more aggressive and competitive were more likely to survive, reproduce, and transmit their genes onto the next generations. Moreover, the fact that males are more aggressive than females is observed in all mammals and explained through sexual selection of partners. This sexual selection usually takes place when females select male partners, promoting inter-male competition for sexual selection and reproduction (Archer 2009; Darwin 1859, 1871; Lindenfors and Tullberg 2011).

Although the purely evolutionary perspective remains valid, research has evolved, incorporating psychological and social elements that helped explain why males remain more aggressive and more involved in crime than females (Archer 2009).

Evolutionary psychology asserts that human behavior, such as the behavior of any other animal, is a product of evolution processes that result from adaptations to ancestral environments, being that these adaptations occurred in a given cultural context and are activated by relevant environmental triggers (Walsh and Beaver 2008). These adaptations to ancestral environments developed to ensure reproduction and survival. In this way, it is reasonable to conclude that both prosocial and morally accepted behaviors and violent/criminal and morally unacceptable behaviors had a degree of usefulness in adapting to ancestral environments, increasing fitness, and ensuring sexual selection (Walsh and Beaver 2008). It is important, however, to note that these adaptations were to ancestral environments, not to the current modern society; thus even if considered maladaptive and morally condemnable nowadays, violent and aggressive behaviors provided some advantage in ancestral environments. Moreover, it is relevant to clarify that specific criminal behaviors are not actual adaptations (genes do not code for specific behaviors such as homicide or fraud) (Walsh and Beaver 2008).

There are several approaches to the evolutionary psychology's study of criminal and predatory behavior, being that most of these approaches focus on the reproductive strategies and behaviors that derive from these strategies. For the most part, research tends to focus on two types of behaviors that are directly related to reproductive strategies: parenting status and mating effort (Walsh and Beaver 2008). The behaviors and characteristics that have been associated to the mating effort are those more commonly associated with criminal behaviors, such as deceitfulness, impulsiveness, sensation seeking, and aggression, while behaviors that derive from parenting are more prosocial and cooperative, including empathy, altruism, and conscientiousness (Daly and Wilson 1988, 1990, 1997; Walsh and Beaver 2008; Wilson and Daly

1992, 1993). Other research has focused more on genetic (Y chromosome) and neurohormonal (testosterone) differences between males and females that account for differences in competition and aggression (e.g., Ellis 2003, 2005).

Matting Effort: Competition, Fitness, and Sexual Selection

Daly and Wilson (1988, 1990, 1997; Wilson and Daly 1992, 1993) applied the notion of sexual selection to studies of violent and criminal behaviors, specifically to homicide and intra-family violence. According to the authors, the sex differential observed in violent behavior reflects the evolution of the human male psyche to become more prone to accept risk-taking behaviors in situations of competition, specifically competition for resources and sexual partners by males (Daly and Wilson 1990, 1997; Wilson and Daly 1985).

Daly and Wilson (1988, 1990, 1997) strongly focused on the study of same-sex homicide, as they considered it to be the “best prototype of crime” (Daly and Wilson 1997, p.54), i.e., homicide is universally considered a serious crime, it is more reliably reported than other forms of crime, and finally it is an extreme form of conflict resolution, allowing to better explore the variety of factors that explain interpersonal conflict throughout the life course (Daly and Wilson 1997). Moreover, homicide rates are much higher among males than females. The authors observed that males had a significantly higher rate of same-sex homicides when compared to females, which is partially explained by intra-male competition for resources (Daly and Wilson 1988, 1990). This competition for resources is greater among males due to a greater variance in fitness among males, when compared to females, and thus a greater variability in sexual selection and reproductive success (Daly and Wilson 1997; Walsh and Beaver 2008). This reinforces the male’s need to focus on matting efforts, which are inherently more competitive and aggressive, while females are more focused on parenting efforts, i.e., on ensuring the survival of their offspring, which is more altruistic and collaborative (Walsh and Beaver 2008).

In line with this assumption, the authors observed that same-sex homicide is more

common among men that have fewer resources (Daly and Wilson 1988, 1990). Specifically, for males with lack of resources, an aggressive challenge of other males may be the only way to ensure successful sexual selection by females and consequent reproduction (Daly and Wilson 1988). This competition for resources, thus, allows to explain both instrumental/rational crimes as well as expressive/irrational crimes (Daly and Wilson 1997).

Although the authors strongly focused on same-sex competition and crimes, as individuals from the same sex tend to compete more as they desire the same type of resources, not all crimes, namely, homicide, are about sexual rivalry, being that many of the criminal actions observed are status crimes (Daly and Wilson 1997; Wilson and Daly 1985).

Daly and Wilson (1997) further propose that individuals are active agents in their behaviors, conducting a cost-benefit analysis. This cost-benefit analysis, which underlies evolutionary psychological explanations of behaviors, is not just a rational decision-making process but rather strongly determined by the process of natural selection (Archer 2009; Daly and Wilson 1997).

Finally, the authors approach the matter of violence against women. To this end, Wilson and Daly focused mostly on intra-family violence in the form of violence against wives (Daly and Wilson 1997; Wilson and Daly 1992, 1993). The authors propose that violence against wives could be explained as a way to deter these females from engaging in behaviors or courses of action that would threaten the male’s fitness and access to resources (e.g., infidelity) (Daly and Wilson 1997; Wilson and Daly 1992, 1993).

Other authors have proposed that rape or sexual violence of males against females might also be a way to overcome competition and ensure reproduction. Cashdan (1993) proposed that males can adopt one of the two reproductive strategies: (a) the Dad strategy, where males commit to a single female, complying to the female preference and helping raise the offspring, or (b) the Cad strategy, where males treat females as conquests, trying to trick or force them into sexual relationships, thus ensuring offspring, but not committing to the female (Cashdan 1993; Walsh and Beaver

2008). On the extreme of the Cad strategy are psychopaths, with reduced emotional responses, and reduced morality, although these tend to be a minority of males (Walsh and Beaver 2008).

Genetic and Neurohormonal Differences: Evolutionary Androgenic Theory

Other researchers have proposed that levels of testosterone may help explain the differences in aggression in males, as well as the increase in aggression that occurs during adolescence. Ellis has developed several studies on the influences of testosterone on behavior and aggression and proposed the evolutionary androgenic theory (ENA), which focuses on explaining offenses that cause harm to other individuals. ENA is based on two propositions: evolutionary and neuroandrogenic (Ellis 2004, 2005).

The *evolutionary proposition* posits that males engage in more violent crimes than females as a result of evolution, specifically due to the female choice, i.e., the selection of mates that were strong protectors and reliable providers, but who also tended to be more competitive. This preference led to a transmission of genes of more competitive males to future generations (Ellis 2004, 2005). This proposition closely matches what was proposed by other evolutionary scholars and studies on sexual selection.

The competitive behavior, nowadays, can be seen as placed along a continuum of competitive/victimization behavior, where the more sophisticated version of this behavior would be associated with profit- or nonprofit-making commerce and a cruder version of this behavior associated to more violent property offenses. Based on this, the author proposes that genes ought to be responsible for a great part of the phenotypic variation observed; also, given the clear differences in competitive and violent behavior between both sexes, it stands to reason that part of this variation would be caused by the Y chromosome (Ellis 2004, 2005). However, the theory does consider the possibility of female criminality; Ellis (2004) proposed that competition will exist in both sexes for resources to rear offspring; however, male competition and victimization behaviors will always surpass that of females. Moreover, females who are able to attract and select males that have access

to more resources will have less competitive tendencies (Ellis 2004).

The *neuroandrogenic proposition* states that testosterone plays a central role in the competitive/victimization behavior. During gestation, different testosterone levels are present in the womb, being these levels much higher for males than for females (produced after the development of the testes); these higher levels of testosterone will masculinize the fetus' brain. The presence of higher level of testosterone can promote the competitive/victimization behavior by causing sub-optimal arousal (decreased sensitivity to adverse consequences), by overstimulating the limbic system, or by leading to a greater neocortical function of the right hemisphere and decreased function of the left hemisphere associated with a less "empathy-based moral reasoning" (Ellis 2005, p. 293). There are two neurological processes that will further influence male competitive victimizing behavior, the individual's intelligence, i.e., their ability to learn, and their cognitive functioning, specifically ability to plan (Ellis 2004, 2005).

In this sense, individuals with more sophisticated behaviors usually present a more efficient cognitive functioning and higher intelligence, being able to better control their competitive expression in a more socially accepted manner, while those individuals with less efficient cognitive functioning and lower learning ability will resort to cruder competitive behaviors (Ellis 2004, 2005). Moreover, males who receive higher levels of exposure to testosterone during critical developmental periods are more likely to become offenders and more likely to remain offending over the life course than males that were exposed to low-moderate levels of testosterone (Ellis 2004).

Conclusion

Overall, evolutionary psychology has a unique perspective and contributions to the explanation of criminality and why it tends to be more prevalent in males. In short, this perspective proposes that males tend to exhibit more competitive and aggressive behaviors, which were evolutionary acquired as a response to ancestral environments

and a need to ensure reproduction and preservation of the species. In modern society, many of the criminal behaviors observed in males can still be explained by sexual and status completion in order to ensure reproduction. These innate tendencies observed in males, much more than in females, might be explained by a greater variability in access to resources observed in males, as well as by increased exposure to androgens, specifically testosterone, which will influence brain structures, specifically promoting the development of areas responsible for more aggressive and competitive behaviors. Taken to the extreme, these behaviors assume more violent and even criminal characteristics, which appear to be more common in males with lack of access to resources as well as those who have lower moral constraints.

Individual perception; Personalized experience; Self-recollection

Definition

Individual perception of intake information or events from a certain moment in time.

Introduction

If there is one proposition on which all psychologists seem to agree, it is that memory is useful. Memory allows organisms to adjust their behavior on the basis of information they acquire ontogenetically, through their experiences with the world. This connection between personal experience, memory, and behavior implies a close relationship between learning and memory. Memory in biological systems always entails learning as it constitutes acquisition of information and learning implies retention of such information (Tulving 1995). Recognizing this, psychologists have long exploited learning paradigms to study the properties of memory.

Self-Observation

Defining the self has challenged psychologists and philosophers for centuries. Self-observation can be defined as the ability to consider what is being observed about the self. It is the self-reflective function that allows one to marshal the resources of self-awareness to alter prediction errors. This ability provides a sense of agency in observing, planning, deciding, and evolving toward a future goal.

Self-Observation as a Social Process

Humans were provided with insightful and novel means of not only expressing but also observing their own experience. This would not be possible if experience was a purely individual and private matter. Instead, we live in an intersubjectively shared and immanently meaningful world. Humans exist as beings in constant communication with others, through which we come to develop shared perspectives on our experience. Introspective self-consciousness is derivative of consciousness of others and not vice versa.

Internal thought is a form of inner dramatization of social conduct and is thus necessarily bound up with social meanings.

Mead (1910) argued that “Other selves in a social environment logically antedate the consciousness of self which introspection analyzes.” In other words, the act of self-reflection presupposes social interaction with others. The introspection involves the incorporation of the other into the self. This conceptual move naturalizes the act of self-reflection by showing that it is an outgrowth of a social process. One’s own gesture does not initially have meaning for oneself. The gesture only has meaning for others, which is their response to the gesture. The establishment of shared meaning requires the existence of stable social institutions with interchangeable social positions – such as buying and selling. Since a vocal gesture can be heard from both sides of a social act in a social practice, it takes on a dual meaning and enables the movement from one social perspective to another. Introspective self-reflection is only possible through a history of interaction with others in social institutions.

Self-Observation and Consciousness

Self-observation results in cognizance of auto-information, such as intentions, expectations, feelings, cognitions, behaviors, and impact on others, and the ability to introspect on one’s own thoughts and to realize the relation of self to one’s social and cultural environment (Stuss and Benson 1983). It is associated with the capacities to distinguish inner from outer reality, pretend from “real” modes of functioning, and intrapersonal mental and emotional processes from interpersonal communications (Fonagy and Target 1997).

This transtheoretical process involves individuals becoming aware of and learning about their own functioning in order to change maladaptive responses and generate new responses for the future (Beitman et al. 2005). In helping the individual focus attention on their own self and idiosyncratic patterns, an external source, such as a psychotherapist, could assist in activating self-observation. This process serves as a tacit common thread woven among the different psychotherapies.

Activation of self-observation is collaboratively employed by practitioner and client within all psychotherapeutic orientations. Self-observation emerges from self-awareness, which, in turn, relies upon consciousness. Consciousness requires mobilizing functional brain structures, including the reticular activating system, and provides the platform for awareness. Awareness is the potential to be conscious of specific content such as objects, persons, and ideas. Self-awareness or “autoeotic consciousness” (Wheeler et al. 1997) is the potential to know the self and the self in context. Self-observation refers to actively scanning one’s inner landscape, mentalization, and the ideas in other people’s minds as well as what others think of the self (Baron-Cohen et al. 2000).

Self-Observation Within Psychotherapy

For many individuals seeking therapy, confusion, distraction, or troublesome symptoms may impede effective self-observation. Storms in the internal and external environment cloud vision, precluding accurate perception of one’s inner landscape. Although self-observation is a normal and adaptive capacity, it can be difficult to preoccupy oneself with such maladaptive thoughts, feelings, and behaviors. A safe and confiding therapeutic relationship offers a client the haven of an interpersonal relationship in which to observe the self, which is necessary to create new ideas and templates of expectations and actions to meet goals. Activation of self-observation thus empowers clients to make more informed decisions, alter prediction errors, create intentions, and plan courses of action (Pally 2004), resulting in increased freedom of choice, increased autonomy, and a wider scope of comprehension (Deikman 1982).

Inceptive and Derived Memory

It is useful to distinguish inceptive from derived memories as they serve survival. Inceptive memories are representations of external input stored in the way they were encoded at the time at which they were first experienced. Many episodic

memories appear to be inceptive; they often contain perceptual detail, proprioceptive information, emotion qualia, a sense of the self as present in the encoding situation, and the sense that the memory is very similar to the original experience. But not all inceptive memories are episodic. It is logically possible to have an inceptive memory about a specific event involving the self without its being episodic in character. It would not be episodic if it lacked the subjective sense of self in space and time that is diagnostic of episodic memory. A derived memory system together with its inferential machinery prepares answers or pre-processes information into usable and ready forms to facilitate decisions and judgments of a specific type that would otherwise be detrimental if they had to be computed from raw data on demand.

Human Memory and Computation

The computational operations that generate derived memory are not limited to mere extraction of information from inceptive memory. A derived memory can contain information not present in any of the inceptive memories on which it was based, generated by procedures that made inferences from the inceptive data. A derived memory may, in some cases, be the output of the same decision process that uses it at a later time. For instance, if one needs to decide at Time 1, on the basis of behavioral episodes, whether Person Y is honest, the conclusion might be stored as a derived memory for use at Time 2. A trait summary is a form of derived memory; a stored episode is an inceptive memory. Because of their advantages, human memory may be full of independent, derived memory stores linked to various inceptive memory stores (Nadel 1994). The linked memory stores of abstracted personality traits and behavioral episodes that exemplify those traits may prove to be a model system that can illustrate properties that are common to many memory stores.

Adaptive Function of Memory and Its Properties

The adaptive function of information storage is intrinsically prospective. It is used to support future decisions and judgments, which cannot be

known in advance with certainty. To the extent that the character of subsequent decisions and judgments can be predicted, the memory system can be tailored to flag relevant information and precompute variables that are required to make them – that is, it can develop a derived memory store. This set is indefinitely large and hence precluded by limitations on computational and memory resources. In functional terms, factors that should govern the number and type of derived memory stores include (a) predictability, the existence of factors, either ontogenetic or phylogenetic, that allows the successful anticipation of likely varieties of future judgment or decision types; (b) importance, the value of those judgments or decisions ought to justify the costs; (c) urgency, the requirement that such judgments be made quickly; and (d) economy, the number of judgments or decisions supported by a derived memory store should be proportionately large with respect to its size. The use of trait summaries in making decisions about social interactions meets all four criteria.

Benefits and Disadvantages

Storing semantic summaries has both advantages and drawbacks. Direct retrieval of precomputed representations (derived memory) economizes on online computation and is fast. But it takes up increasing amounts of memory the larger the set of representations that must be precomputed and on tap and may provide information that is no longer up to date. In contrast, procedures triggered online that take inceptive memories as input economize on derived memory and provide up-to-date information. But they are expensive computationally and increasingly slow, the more computational steps that are involved. An architecture designed functionally would be shaped by these trade-offs, using different mixes of memory versus computation for different types of adaptive problem (Pinker 1997, 1999). Decisions about personality traits provide a case in point.

Trait Summaries

Dynamically, when the data set of relevant events is small, judgments about personality traits appear

to be made predominantly based on retrieved behavioral episodes (Klein et al. 1997; Klein and Loftus 1990). As the behavioral evidence grows, judgments are increasingly made by accessing an emerging trait summary and decreasingly by accessing relevant episodes. When the amount of experience is high, the semantic summary is well developed, and trait judgments are made by accessing this knowledge (Klein et al. 1997; Klein and Loftus 1990). This process is faster than retrieving and considering individual instances (Klein et al. 1992), and it bypasses and inhibits this other judgment route. Evidence suggests that semantic trait summaries are constructed on the basis of the same set of behavioral episodes that are input into the episodic store (Sherman 1996), although supplementation from other sources of information has not been ruled out. Neurologically impaired individuals who exhibit an inability to retrieve individual events show no apparent impairment in their ability to make accurate trait judgments (Klein et al. 1999) and even maintain the ability to revise their trait judgments based on new episodes they cannot recall. This suggests retrieval of behavioral episodes for trait judgments lies outside conscious awareness. It further argues that either updating of semantic information occurs as each episode is experienced or else the procedures involved in updating do not require conscious access to the episodic store (Sherman and Klein 1994).

Stored Episodes

Trait summary is valuable in human evolution and survival as it fosters speedy access to information and avoidance of redundant and costly computation. Nevertheless, a summary lacks information present in the episodes from which it was derived. Retrieving a trait summary may be faster than constructing a judgment online from a database of episodes, but it is necessarily less accurate. Maintaining a database of inceptive, episodic memories solves several problems that a trait summary cannot. New information may cause previous episodes to be reinterpreted, drastically changing one's judgments of a person or a situation. Keeping a database of episodes is helpful even when a drastic reinterpretation of previous

events is not called for. Judgments can be revised in light of new information.

Scope Hypothesis

The scope hypothesis asserts that the function of priming inconsistent episodes is to place boundary conditions on the scope of a semantic summary. An excellent package of speed and accuracy can be engineered into a decision system by jointly activating a trait summary and episodic memories that are inconsistent with it. Trait self-descriptiveness judgments should activate trait-inconsistent, but not trait-consistent, behavioral episodes. In the event that scope hypothesis is supported, one would expect that trait-inconsistent episodic memories are primed by retrieval of a trait summary from semantic memory.

Boundary Conditions on the Scope of Generalizations

To rely on semantic memory alone is to sacrifice accuracy for speed as trait summaries lack the resolution of an episodic memory. Although trait judgments have predictive validity, the behavior of an individual manifests a great deal of situation specificity (Funder 1995). Episodic memories are situation-specificity incarnate. They are records of how particular people behaved in specific situations. A system engineered to retrieve, along with a generalization, episodes that place boundary conditions on its scope would achieve the best of both worlds: speed courtesy of semantic memory and accuracy courtesy of episodic memory.

Decision Context

The decision context should determine when boundary conditions are needed and which kinds of episodes would be relevant. Because decisions regarding personality traits are not amenable to all-or-none answers, it would be reasonable to assume that the trait summary takes a quasi-quantitative form. Thus, when the individual is asked if a certain trait describes them, possible answers might be “usually,” “sometimes,” or “rarely.” Boundary conditions would be episodes

in which the behavior did not meet the criteria for that trait. This should be true for any level the trait summary specifies, even “rarely.” This is because the decision context calls for a generalization about it; the function of activating episodes is to place boundary conditions on that generalization. The issue is “How often is Person Y friendly, and under what conditions is she or he not?” The decision rule activated is designed to make a judgment about the trait being asked about, whether the question originates with another person or with the individual making the judgment.

Different decision rules are designed to retrieve different kinds of information from memory. The type of decision being made matters, because that determines which search engine gets activated, which will determine which array of memory systems gets searched. When asked to trait-categorize their own behavior, subjects should retrieve a trait summary and episodes inconsistent with the trait they are being asked about.

The Self-Study

It was examined whether accessing a trait summary about the self would prime trait-inconsistent episodes but not trait-consistent ones (Klein et al. 2001). Subjects were presented with a list of trait adjectives and asked to perform one of three tasks with them. The describe task asked subjects to decide whether the stimulus trait describes them; the recall task asked subjects to retrieve a specific instance in which they manifested the stimulus trait; and the define task asked subjects to generate a definition for the stimulus trait. If the scope hypothesis is correct, then deciding whether a trait is self-descriptive will activate a summary representation and episodes inconsistent with the trait being asked about. Empirically, one should observe two things.

The results showed that deciding whether a trait describes oneself facilitates retrieval of trait-inconsistent episodes, which suggests that these judgments activate memories of behaviors inconsistent with the trait being judged (Klein et al. 2001). By contrast, there was no evidence that trait self-descriptiveness judgments

facilitated retrieval of trait-consistent episodes. Based on the outcome of the experiment, it is inferred that decisions about whether a trait describes oneself do not activate trait-consistent behavioral memories. That trait-inconsistent, but not trait-consistent, episodic memories are primed by retrieval of a trait summary from semantic memory is just what one would expect if the scope hypothesis were correct.

The Mother Study

This study had two primary objectives; first, it aimed to extend the generality of the scope hypothesis by testing whether judgments about a well-known other also conform to its predictions and, second, to address the finding that activation of trait-inconsistent behaviors occurred regardless of whether the trait judged fell in the high, medium, or low self-descriptiveness categories. This finding can be accommodated within the scope hypothesis by assuming that trait knowledge about the self is represented in summary form across levels of trait self-descriptiveness. According to the model of mental representation of trait knowledge about others, one's representation of a person's traits varies with the amount of experience one has had with that person. If the amount of experience is not sufficient to support abstraction, then trait knowledge will be represented only at the level of behavioral memories. Trait judgments about the person, therefore, must be based on inceptive behavioral memories, that is, on episodes. However, as the amount of experience becomes sufficiently large, trait knowledge is increasingly likely to be abstracted and represented in summary form.

The study results illustrated that for traits highly descriptive of one's mother, ones for which a summary should exist, trait-inconsistent episodes were primed, but trait-consistent ones were not. For traits only moderately descriptive of one's mother, ones for which there should be no summary, the opposite pattern was found. Trait-inconsistent episodes were not primed, but trait-consistent ones were.

The results of this study strongly support the scope hypothesis as they allow for comparisons in

priming when trait summaries are present versus absent. When a decision is made by accessing a trait summary, search engines should simultaneously retrieve inconsistent episodes to provide information about the conditions under which the summary ceases to be useful. Thus, trait-inconsistent behaviors were primed when a decision about one's mother was made by accessing summary representations of her traits. But when summary representations were absent, they could play no role in decision-making. This explains why trait-inconsistent behaviors were not primed in the medium-descriptive condition. According to the scope hypothesis, when no generalization has been accessed during a decision task, there is no representation whose scope needs to be delimited.

Summary Representation

Humans are sensitive to the summary statistics of the visual world. They derive this information from complex scenes, often without explicit awareness. The visual system is susceptible to summary statistical stimuli about group or ensemble characteristics in the natural world. The summary statistics are derived across a host of visual domains, ranging from average orientation to the average expression from crowds of faces. The ease with which people can detect an outlier suggests their representations of categories of objects incorporate some notion of what is average and of the upper and lower limits in the normal variability within the dimension in question. When viewing a set of objects, a particularly large or small member of the set will stand out and will be readily detected (Hodsoll and Humphreys 2001).

Summary Representation as a Function in Scope Hypothesis

It has been argued that generalizations from semantic memory allow speedy decisions, but at the cost of accuracy, whereas episodic memories provide accurate, situationally specific, information, but at the cost of speed. Nevertheless, both speed and accuracy can be engineered

into a decision-making system, if the system is designed to retrieve both kinds of information in the right combination. A generalization is most useful when its scope is delimited, that is, when it is accompanied by information specifying those situations in which it does not apply. Episodic memories that are inconsistent with the generalization can facilitate this function because they are broadband encodings of specific situations in which the generalization fails to predict the outcome. Interpretively, this task analysis constitutes the scope hypothesis. A decision rule needs a search engine that looks for summary information in semantic memory and, on retrieving it, looks for episodic memories that are inconsistent with that summary, ones that place boundary conditions on the summary's scope.

The Statistical Nature of Summary Representation

Research suggests that when subjects attend to a particular dimension of a set of items presented over an extended duration, they quickly learn about the central tendency of the set. However, it is unclear whether such learning can occur incidentally, when subjects are not attending to the relevant dimension of the set. Chris Oriet and Kadie Hozempa (2016) studied incidental summary representation over time exploring whether subjects could reproduce global statistical properties of a set presented over an extended duration when oriented to task-irrelevant properties of the set. Subjects were tested for their memory of its mean, its smallest and largest exemplars, the direction of its skew, and the relative distribution of the items. Subjects were able to accurately recall the average size circle, as well as the upper and lower boundaries of a set of 4200 circles displayed over an extended period. This suggests that even without intending to do so, they were encoding and updating a statistical summary representation of a task-irrelevant attribute of the circles over time. Such incidental encoding of statistical properties of sets is thus a plausible mechanism for establishing a representation of typically in category membership.

Change Blindness

The failure to notice differences in sequential scenes or images is a well-established phenomenon, suggesting that humans have a limited visual awareness from one moment to the next (Mitroff et al. 2002; Rensink et al. 1997). Although, on the surface, change blindness seems to suggest a sparse visual representation, an abundance of recent research has supported the notion that a failure to represent visual information is unlikely to drive this phenomenon. Much of the incoming visual input is preserved in spite of change detection failures (Beck and Levin 2003; Hollingworth 2003). For instance, Beck and Levin (2003) showed that observers could identify an object change in the absence of a durable representation of that object. Mitroff et al. (2004) demonstrated that this durable representation could potentially be used to aid in object identification. Hollingworth and Henderson (2004) found that visual scene information was preserved even when observers failed to detect a rotation in the scene. Research suggests that despite the limited conscious access revealed by change detection experiments, the "gist" of a scene remains accessible (Oliva and Torralba 2001; Potter 1976; Thorpe et al. 1996).

Given the fundamental and ubiquitous nature of summary statistical representation, Jason Haberman and David Whitney (2011) tested whether this kind of information is subject to the attentional constraints imposed by change blindness. They showed that information regarding the summary statistics of a scene is available despite limited conscious access. In a novel experiment, they found that while observers can suffer from change blindness (i.e., not localize where change occurred between two views of the same scene), observers could nevertheless accurately report changes in the summary statistics about the very same scene. In the experiment, observers saw two successively presented sets of 16 faces that varied in expression. Four of the faces in the first set changed from one emotional extreme to another in the second set. Observers performed poorly when asked to locate any of the faces that changed (changed blindness). However, when asked about the ensemble (which set was happier, on average),

observer performance remained high. Observers were sensitive to the average expression even when they failed to localize any specific object change. That is, even when observers could not locate the very faces driving the change in average expression between the two sets, they nonetheless derived a precise ensemble representation. Thus, the visual system may be optimized to process summary statistics in an efficient manner, allowing it to operate despite minimal conscious access to the information presented.

The Role of Attention

As the perceptual phenomenon occurs when a change in a visual stimulus is introduced, the observer does not notice it. Observers often fail to notice major differences introduced into an image, while it flickers off and on repeatedly. Researchers have found that shifting a person's attention, such as causing distraction, leads to increased change blindness. There is already evidence that summary statistical information operates beyond the focus of attention (Alvarez and Oliva 2008). Nonetheless, this has only been demonstrated with low-level features, such as features thought to be analyzed at the earliest stages of cortical visual processing, including orientation, contrast, and motion direction, which are expected to be processed in parallel (Watamaniuk and McKee 1998).

Conclusion

The aforementioned type of statistical summary learning appears to occur without conscious intent. Information taken in by the human visual system allows individuals to form statistical representations of sets of items. Memory evolved to supply useful, timely information to the organism's decision-making systems. Hence, decision rules, multiple memory systems, and the search engines that link them should have coevolved to mesh in a coadapted, functionally interlocking way. This adaptationist perspective suggested the scope hypothesis: When a generalization is retrieved from semantic memory, episodic memories that are inconsistent with it should be

retrieved in tandem to place boundary conditions on the scope of the generalization. Using a priming paradigm and a decision task involving person memory, the researchers tested and confirmed the scope hypothesis. The results support the view that priming is an evolved adaptation. They further show that dissociations between memory systems are not absolute and that independence exists for some tasks but not others.

Definition

Certain personality features predict individuals' deployment of mate retention behaviors.

Introduction

Benefit-provisioning personality features (those associated with greater likelihood of providing benefits to one's partner) are significantly correlated with certain types of mate retention behaviors.

The popular Big Five Model of Personality describes a taxonomy of personality broken down into five factors: openness, conscientiousness, extraversion (or surgency), agreeableness, and emotional stability (or neuroticism) (Goldberg 1992; McCrae and Costa 1987; Norman 1963). Mate retention behaviors result from evolved psychological mechanisms in response to the adaptive problem of retaining a mate in a relationship (Buss 1988).

Mate retention behaviors are described in a taxonomy of five categories (*direct guarding*, *intersexual negative inducements*, *intrasexual negative inducements*, *public signals of possession*, and *positive inducements*) further broken down into 19 mate retention tactics. Miner et al. (2009) demonstrated that mate retention behaviors can usefully be divided into two domains: *cost inflicting* (consisting of direct guarding, intersexual negative inducements, and intrasexual negative inducements) and *benefit provisioning* (public signals of possession and positive inducements).

A limited but growing amount of research has begun to investigate the relationship between Big Five personality factors and mate retention behavior, including benefit-provisioning mate retention. For example, de Miguel and Buss (2011) investigated the relationship between Big Five personality factors and the 19 tactics of mate retention. They found that neuroticism was positively correlated with many (16 of 19) mate retention tactics, including some which fall under the Miner et al. (2009) domain of benefit provisioning (e.g., appearance enhancement and

submission/abasement). de Miguel and Buss (2011) also found a positive relationship between conscientiousness and appearance enhancement and a negative relationship between conscientiousness and cost-inflicting mate retention. Agreeableness was negatively correlated with cost-inflicting mate retention but was not related to benefit provisioning. Extraversion was associated with both cost-inflicting (e.g., jealousy induction, punishment of infidelity threats) and benefit-provisioning (e.g., sexual inducements, appearance enhancement) domains of mate retention behavior. Openness was found to be positively correlated with sexual inducements and the use of love and care, both benefit-provisioning tactics of mate retention.

McKibbin et al. (2014) examined the relationship between heterosexual men's mate retention and both men's personality and their partner's personality and found mixed results. As in de Miguel and Buss (2011), men's neuroticism was positively correlated with both domains of mate retention, based on men's and their partner's reports. However, their partner's neuroticism was not related to men's mate retention. Conscientiousness was generally not related to men's mate retention, although men's reports of their partner's conscientiousness were related to benefit provisioning. Men's reports on their own or their partner's agreeableness were not related to mate retention in either domain. However, women's reports of their partner's agreeableness were negatively associated with cost inflicting and positively associated with benefit provisioning.

Conclusion

Researchers have only recently begun to investigate how individuals' personality may affect their mate retention behavior. More work must be done before firm conclusions may be drawn regarding the relationship between these variables. Importantly, research highlights that men's and women's perceptions of themselves and each other differ, and these differences may affect the deployment of mate retention behavior. More work is needed to expand this domain of research.

Definition

Mate poaching is a behavior intended to attract someone who is already in a romantic relationship in order to form a short- or long-term mating alliance with her/him.

Introduction

Mate poaching is a frequent and potent form of romantic attraction in humans throughout the world (Schmitt et al. 2004; Schmitt and Shackelford 2008). Research on the large sample of participants from 53 nations across the 10 world regions has found that around 60% of men and 40% of women admitted trying to poach someone else's partner for short-term sexual relationship or a new long-term mating alliance, while nearly 70% of participants reported that someone had tried to poach them either for short-term or long-term relationship (Schmitt et al. 2004). Identifying personal characteristics related to mate poaching is an important step in understanding its causes and consequences. Namely, personality traits are related to the creation of adaptive problems, as well as to their solution especially in socially relevant situations such as mateships (Buss 2010). Previous research have consistently shown that personality characteristics are related to different mate poaching experiences, such as trying to attract a person who was already in a romantic relationship, the success in poaching attempts, the experience of being a target of poaching, being successfully poached, and the experience of having others attempted to obtain someone's partner away (being the victim of poaching). These aspects of mate poaching are usually assessed by Anonymous Romantic Attraction Survey (ARAS; Schmitt and Buss 2001) and the most frequently examined personality characteristics related to mate poaching are Big-five personality traits, Dark Triad (DT) traits, and Sexy Seven personality attributes (Schmitt and Buss 2000).

We have identified only 12 studies dealing explicitly with the relationships between

personality characteristics and different mate poaching experiences. All of them are cross-sectional, mostly carried out on the samples of college or university students, and rarely community samples. They examined mate poaching for a short-term, and only three of them focused on mate poaching for both short- and long-term sexual relationship. The largest amount of data have been obtained from International Sexuality Description Project (ISDP; Schmitt et al. 2004, 2017; Schmitt and Jonason 2015; Schmitt and Shackelford 2008) that involved more than 30,000 participants from around 50 nations and 11 world regions.

Personality Correlates of Mate Poaching Attempts

Regarding five-factor personality traits, agreeableness and to a lesser degree conscientiousness were the most consistently negatively, while extraversion positively related to poaching attempts in both women and men (Kardum et al. 2015; Schmitt and Buss 2001; Schmitt et al. 2004; Schmitt and Shackelford 2008). Only one study found low positive correlations of openness and neuroticism with poaching attempts, and the latter only in women (Schmitt and Shackelford 2008). On the level of higher order factors, alpha (stability or general avoidance tendencies) and beta (flexibility or general approach tendencies) (Larsen and Augustine 2008), poaching attempts were positively related to beta factor in both women and men and negatively with alpha factor in men. Regarding DT traits, overall psychopathy was the most consistently related to poaching attempts in both women and men (Jonason et al. 2010b; Kardum et al. 2015; Williams et al. 2005). This trait as well as its specific components, egocentricity, antisocial behaviors (Centifanti et al. 2016), and primary psychopathy (Khan et al. 2017) have been found to be moderately related to poaching attempts. Narcissism was also positively related to poaching attempts on the whole sample (Jonason et al. 2010b), and Narcissism and Machiavellianism on the samples of women and

men separately (Kardum et al. 2015). Regarding the components of Narcissism, mate poaching attempts were across 11 world regions, the most strongly positively related to the socially maladaptive factor called Exhibitionism/Entitlement within the two-factor model of Corry et al. (2008) and with the relatively maladaptive facets of Exhibitionism, Exploitativeness, and Authority within the seven-factor structure of Raskin and Terry's (1988) model (Schmitt et al. 2017). DT traits composite was moderately positively related to poaching attempts on the whole sample (Jonason et al. 2010b) as well as on the samples of women and men, and it better predicted poaching attempts than alpha and beta factors (Kardum et al. 2015). Additionally, poaching attempts were moderately positively related to sociosexuality (Grundler et al. 2013), lowly positively to secure, dismissing, preoccupied and fearful attachment in both women and men (Schmitt and Jonason 2015), as well as to borderline personality disorder (Centifanti et al. 2016). Furthermore, poaching attempts were related to two of the Sexy Seven personality attributes (Schmitt and Buss 2000), negatively to relationship exclusivity (whether one is promiscuous and adulterous), and positively to erotophilic disposition (obscurity, indecency, and lust) in both women and men (Centifanti et al. 2016; Schmitt and Buss 2001; Schmitt et al. 2004).

To summarize, we could describe a person prone to mate poaching attempts as one with a callous affect, lower empathy and anxiety, interpersonally manipulative, antisocial, impulsive, egocentric, with feelings of superiority and entitlement, disagreeable, unreliable, extraverted, indecent, and promiscuous. It seems that psychopathy characteristics most strongly predict poaching attempts in women as well as in men probably because they include behaviors necessary to enact high mating effort strategy, like manipulateness, that helps initiating numerous shallow relationships, promiscuity that may increase the number of potential offspring, and low conscientiousness that enables leaving romantic relationships and ignoring parental responsibilities (Wiebe 2004).

Personality Correlates of Mate Poaching Success

From the five-factor personality traits, openness (Kardum et al. 2015; Schmitt et al. 2004), extraversion, and higher order beta factor were positively related, while agreeableness was negatively related to mate poaching success in both women and men (Kardum et al. 2015). Regarding DT traits, overall psychopathy (Jonason et al. 2010b; Kardum et al. 2015) as well as its components – erratic lifestyle, criminal tendencies, and interpersonal manipulation – correlated positively with poaching success in women, while erratic lifestyle, criminal tendencies, and cold affect with poaching success in men (Sunderani et al. 2013). Narcissism was also positively related to poaching success on the whole sample (Jonason et al. 2010b) as well as on women and men separately, while Machiavellianism was positively related to poaching success only in women (Kardum et al. 2015). Consequently, overall DT was positively related to poaching success on the whole sample (Jonason et al. 2010b) as well as on the samples of both women and men (Kardum et al. 2015). Additionally, self-esteem was found to be positively related to poaching success only in men (Sunderani et al. 2013). Four of Sexy Seven personality attributes were related to poaching success. Sexual attractiveness (facets of beauty and seduction) and erotophilic disposition were positively related, while relationship exclusivity and sexual restraint (abstinence and prudishness) were negatively related to poaching success in both women and men (Schmitt and Buss 2001; Schmitt et al. 2004). Therefore, personality characteristics of a person successful in mate poaching overlap with those who attempt poaching. However, successful poachers possess some distinctive characteristics that may signal their quality as potential partners, such as inventiveness, originality, curiosity, artistic interests (trait of openness), self-esteem as well as attractiveness, allurements, eroticism, amorousness, and seductiveness (sexual attractiveness factor of the Sexy Seven personality attributes).

Personality Correlates of Being a Target of Mate Poaching

Regarding five-factor personality traits, it has been found that extraversion, openness, and consequently higher order beta factor are the most consistently positively related to being a target of mate poaching in women as well as in men (Kardum et al. 2015; Schmitt and Buss 2001; Schmitt et al. 2004). Additionally, some studies found that neuroticism was positively related (Schmitt and Shackelford 2008) and agreeableness was negatively related to being a target of poaching in women and men (Kardum et al. 2015; Schmitt and Shackelford 2008). Conscientiousness was lowly and inconsistently related to this aspect of mate poaching, because some studies have found negative relationships in women and men (Schmitt and Shackelford 2008), and some positive, but only in men (Kardum et al. 2015). DT traits were more strongly related to being a target of poaching than five-factor personality traits. All DT traits as well as DT composite were positively related to this poaching experience in women and men separately (Kardum et al. 2015), while on the whole sample, Jonason et al. (2010b) found positive relationships for psychopathy, Narcissism, and DT composite, and Khan et al. (2017) for primary psychopathy. Furthermore, being the target of poaching was positively related to sociosexuality in women and men separately (Grundler et al. 2013). When the Sexy Seven sexuality attributes are concerned, sexual attractiveness and emotional investment (love and romance) were positively related, while relationship exclusivity negatively related to this aspect of mate poaching (Schmitt and Buss 2001). The results obtained from ISDP show that sexual attractiveness and erotophilic disposition were positively related, and relationship exclusivity negatively related to being a target of poaching in women as well as in men (Schmitt et al. 2004). Main characteristics of a person who has experience of being a target of poaching are those comprised in DT traits and those aspects of five-factor personality traits related to approach motivation, such as extraversion and openness as well as sexual attractiveness and generally higher interest in sexuality.

Personality Correlates of Being Successfully Poached

From the five-factor personality traits, this aspect of mate poaching experiences was the most strongly negatively related to agreeableness and conscientiousness in women and men (Schmitt and Buss 2001; Schmitt et al. 2004). Being successfully poached was also positively related to neuroticism (Schmitt and Buss 2001), extraversion, as well as higher order beta factor, but only in men (Kardum et al. 2015). DT traits, especially psychopathy, Narcissism, and DT composite, were more highly related to being successfully poached than five-factor personality traits (Jonason et al. 2010b). Similarly, the components of psychopathy, mostly interpersonal manipulation, and to a lesser degree cold affect and erratic lifestyle, were also positively related to being successfully poached in women (Sunderani et al. 2013). On the sample of women, psychopathy, Machiavellianism, and DT composite and on the sample of men, all DT traits and DT composite were positively related to being successfully poached (Kardum et al. 2015). Additionally, socio-sexuality was also positively related to this aspect of mate poaching experience in women as well as in men (Grundler et al. 2013). Regarding the Sexy Seven sexuality attributes, erotophilic disposition was positively related, while relationship exclusivity, gender orientation (masculinity) and emotional investment negatively related to being successfully poached (Schmitt and Buss 2001). The results obtained from ISDP show that relationship exclusivity was negatively related, while erotophilic disposition positively related to being successfully poached in women as well as in men, while it was negatively related to emotional investment only in women (Schmitt et al. 2004). To summarize, a person who is liable to be successfully poached could be described as disagreeable, unconscientious, psychopathic, narcissistic, and machiavellistic as well as having promiscuous and adulterous tendencies.

Personality Correlates of Being a Victim of Mate Poaching

Being the victim of poaching has been rarely explored in relation to personality characteristics.

This aspect of mate poaching was positively related to psychopathy, Narcissism, and DT composite (Jonason et al. 2010b). Although it was positively related to extraversion, higher order beta factor, psychopathy, Narcissism, and overall DT in women, while negatively to agreeableness, and positively to psychopathy, Narcissism, Machiavellianism, and overall DT in men, regression analyses show that only Narcissism is a positive predictor of this aspect of poaching in women, and DT composite in women and men (Kardum et al. 2015). Additionally, Khan et al. (2017) have found that being the victim of poaching was positively related to Borderline Personality Disorder. Notwithstanding that being a victim of poaching is the least predictable aspect of poaching experiences, personality characteristics that best describe victims of poaching are those comprised within DT traits. On the one hand, these personality characteristics are undesirable to their partners, and may facilitate their real sexual unfaithfulness, and, on the other hand, they may make them more suspicious to the faithfulness of their partners (Massar et al. 2017). Both of these processes could be facilitated by assortative mating in personality traits. Because people tend to match up with others on specific characteristics including DT traits (Kardum et al. 2017), being the victim of poaching may be driven by the choice of a partner whose characteristics facilitate their unfaithfulness.

Sex Differences in Personality Correlates of Poaching Experiences

Some sex differences in the relationships between personality and mate poaching experiences have been found. The results of aforementioned studies show that extraversion was somewhat more strongly related to poaching attempts in men (Kardum et al. 2015; Schmitt et al. 2004; Schmitt and Shackelford 2008), while Narcissism better predicted poaching attempts in women (Kardum et al. 2015). Men who experience more poaching success had higher scores on openness (Kardum et al. 2015; Schmitt et al. 2004) and self-esteem (Sunderani et al. 2013), while women had higher scores on DT traits and DT composite (Kardum

et al. 2015). Being the target of poaching was more highly linked to conscientiousness and openness in men, and DT traits and neuroticism in women (Kardum et al. 2015; Schmitt and Shackelford 2008), while being successfully poached was related more to extraversion and DT traits in men than in women (Kardum et al. 2015). Socially undesirable traits of disagreeableness, Machiavellianism, and sociosexuality were more highly associated with being the victim of poaching in men, while this aspect of mate poaching was related more to extraversion and Narcissism in women (Grundler et al. 2013; Kardum et al. 2015). Therefore, women and men have somewhat different set of characteristics related to all types of poaching experiences. Additionally, personality correlates of mate poaching experiences in women are more homogeneous across different types of experiences than those in men. They mostly include socially undesirable DT traits indicating sexual desire, a tendency toward recreational sex (Carter et al. 2014) and the lack of moral concerns (Arvan 2013).

Personality correlates of mate poaching experiences in men are more heterogeneous and depend more upon the type of experience. Approach motivation, sensation-seeking, sociability, and social visibility included in extraversion are more important for poaching attempts, while their poaching success is more determined by socially desirable traits such as openness and self-esteem, which indicate their higher mating quality. Similarly, highly valued traits of conscientiousness and openness are more strongly related to being a target of poaching, while the traits indicating approach motivation and a tendency toward the increase in reproductive success with minimal investment (DT traits) to being successfully poached. Personality traits related to poaching attempts and being successfully poached in men, both indicating their tendency to short-term sexual strategy, are those based on immediate rewards and gratification, enabling fast life-history strategy (Jonason et al. 2010a). Men's traits related to poaching success and being the target of poaching, two poaching

experiences that depend on how potential partners perceive their mating qualities, are highly valued traits, and are probably the consequences of women's choosy and discriminative nature regarding mate choice (Trivers 1972).

Cross-Cultural Universality of the Relationship Between Personality and Mate Poaching Experiences

It is important to identify whether personality characteristics related to mate poaching experiences are universal across cultures, i.e., features of human nature, or whether they are culturally unique, i.e., dependent upon specific sexual culture. The only source of information about this issue until now is data from ISDP and ISDP-2 (Schmitt et al. 2004, 2017; Schmitt and Jonason 2015; Schmitt and Shackelford 2008). Relationships of five-factor personality traits and Sexy Seven Sexuality Attributes with poaching attempts and success as well as being the target of poaching and being successfully poached were similar across most cultures and world regions (Schmitt et al. 2004). Furthermore, Narcissism (including two broad factors and seven traditional facets of NPI) was reliably linked to poaching attempts across all major world regions of the ISDP-2 – North America and Central/South America, Northern, Western, Eastern and Southern Europe, Middle East, Africa, Oceania, South/South East and East Asia (Schmitt et al. 2017). Additionally, culturally consistent relationships of short-term mate poaching and all forms of attachment insecurity were found in women, with preoccupied attachment demonstrating the most consistent links across different cultures. The relationships between attachment insecurity and mate poaching were much smaller and less consistent across world regions among men (Schmitt and Jonason 2015). In sum, although there are only few cross-cultural studies, the similar associations of personality and mate poaching experiences worldwide suggest that psychological mechanisms of mate poaching

are universal and not limited to any specific sexual culture.

Conclusion

It seems that personality characteristics are meaningfully related to various mate poaching experiences. These relationships are small to moderate, with poaching attempts, poaching success, and being the target of poaching more strongly related to personality characteristics than being successfully poached and being the victim of poaching. Personality characteristics that are the most strongly related to different poaching experiences are DT traits and sexuality attributes, followed by five-factor personality traits and attachment styles. Patterns of relationships between personality characteristics and mate poaching experiences are partly different in women and men, being more distinctive in men, which is probably the result of gender differences in evolved sexual strategies. Additionally, the links between mate poaching experiences and personality characteristics are largely cross-culturally universal and similar for mate poaching for short- as well as long-term relationships.

Introduction

Personality refers to stable patterns in the ways that an individual thinks, behaves, and emotes across situations and the passage of time. An appreciation of personality is central for understanding oneself and navigating the social world. McAdams and Pals (2006) have argued that an evolutionary perspective on psychology is a powerful approach to understanding personality as it sheds light on the origins of universals of human nature, the ways in which humans are similar to certain others, and the manner with which each human is distinct. An evolutionary approach to personality also draws attention to the impact of our nonhuman heritage: Aspects of our human genome, physiology, and behavioral phenotype are shared across species. Given the eusocial nature of the human species, many of our traits have been shaped by contingencies of cooperation and competition for survival resources with members of our own species and culture. Thus, an evolutionary perspective of personality takes into account that diverse classes of behavior are emitted by an organism, and certain behaviors are selected by environmental contingencies over

both phylogenic (ancestry) and ontogenic (personal lifetime) timeframes.

Evolutionary and genetic approaches to behavior have sometimes been construed as genetic essentialism, the belief that behavior and individual differences are determined by genes, and fatalistic viewpoints implying genetically influenced outcomes are immutable. Such views have troubling implications for behavioral health problems such as personality disorders as they may increase mental health stigma and deter individuals from seeking treatment (Kong et al. 2017). Emerging research, however, is revealing the epigenetic processes whereby DNA is modified by the environment. Thus, there is growing appreciation of malleable nature of personality (Kong et al. 2017; Roberts and Jackson 2008). As such, any momentary glimpse of personality is the result of the individual's ancestry, culture, and personal life experiences, with significant potential for development and modification into late adulthood.

Defining Personality

Merriam-Webster (2017) offers several definitions of personality including “the complex of characteristics that distinguishes an individual or a nation or group; *especially*: the totality of an individual's behavioral and emotional characteristics.” Although different situations present with different expectations of our behavior, many of us have an inherent or intuitive appreciation for our own stable sense of self. Our preferences, values, and ways may remain consistent over time, despite that our outward behavior may vary substantially across situations. Likewise, we are aware of the patterns, personalities, and traits of the individuals with whom we interact repeatedly. We may be aware of some colleagues and friends who are more dependable than others. Certain neighbors are reliably more gregarious, quick-tempered, or neurotic than others. When these individual differences in our own behavior or the behavior of others result in beneficial consequences such as friendship, affiliation, and cooperation they can be source of predictability and even comfort in an ever changing world. Whereas

patterns of ineffective behavior such as inattentive quirks may be source of bemusement, entrenched patterns of mistrust and aggressiveness may be a substantial source of misery for the individual or those around them.

Heritability and Behavior

Behavior and personality evolve when diversity exists in behavioral phenotypes and their underlying genotypes. Traits that increase reproductive fitness of the organism or their kin are more likely to be passed on to progeny. Traits that are passed on to progeny or offspring through reproduction are said to be inherited. The term heritability refers to the *proportion* of variability in a trait that is explained by genetic factors. A number of methods can be used to estimate heritability with varying degrees of complexity. For instance, significant correlations between personality traits of parents and offspring suggest that traits may be inherited. However, such methods are not able to discern the extent to which the shared variation in personality traits is explained by common a common underlying genotype versus common experiences in similar environments. Twin studies are useful paradigm for estimating heritability, as monozygotic twins share nearly identical DNA, and so differences in their personalities can be attributed to differences in their personal life experiences. Potential environmental impacts can be further parsed by comparing correlations in traits to correlations of traits of monozygotic twins who were reared apart, and with correlations of traits dizygotic twins who share similar environments but only roughly 50% of their DNA (Krueger et al. 2008). It has often been cited that approximately half of all variation in personality traits is accounted for by genetic differences (Turkheimer 2000).

Inheritance and heritability are often confused as identical constructs leaving some to believe that estimates of heritability indicate the degree to which a behavior or personality trait is *caused* by differences in genes. Hypothetically, if environments could be made to be identical for a group of individuals, then all differences in their

personalities would be explained by genetic differences. Inversely, if a group of individuals had identical DNA, then all differences in their personalities should be explained by their environments, or measurement error. Yet it would be erroneous to assume that the genome plays no causal role in this latter, as without a genome there would be no nervous system let alone any organism or individual. This realization has sparked considerable interest in gene–environment interactions, and several methodologies for probing these interactions will be described later.

A Brief History of Personality Psychology

Despite the intuitive appeal of the meaning of personality, a substantial amount of work was required to effectively operationalize personality in a manner that was reliable, valid, and broad enough in scope to be a useful construct in the behavioral sciences. As with many other foci of psychology, personality can be abstracted from discrete observations of public behavior, but also the subjective thoughts, and emotions and preferences of the individual. In 1953, in response to years of speculative analysis into Freudian personality dynamics and the failure of personality theory to inform psychotherapy of the time, B.F. Skinner eschewed personality as a causal factor in the explanation and control of behavior. Rather than an explanation for behavior, personality was viewed as a pattern of behavior to be explained in terms of its environmental antecedents and consequences. Whereas the early radical behavioral approach acknowledged the importance of evolutionary forces in shaping behavior, the research agenda emphasized the practical importance of studying operant and respondent control of behavior and intervening with the goal of addressing immediate problems in human behavior. Personality Psychology would face similar criticism in the 1970s as part of the “trait-situation” debate (McAdams and Pals 2006; Revelle 2016; Roberts and Jackson 2008). Personality psychology was the subject of further criticism in the person-situation debate when some psychologists questioned the utility of personality construct given that behavior varies so

widely based on situational demands. Additional work has since documented those independent ratings and cross-situations correlations in behavior. Meta-analyses and other reviews have consistently shown that personality is particularly useful for the scientific prediction personal and professional health and well-being.

Of the early leaders of personality psychology, Hans Eysenck remains the most impactful on the contemporary personality psychology field, and he is often recognized for his conceptualization of personality from a biological perspective (Revelle 2016). His approach to personality was unique in that it integrated methods from a number of fields of psychology including psychometrics, experimental psychology, and behavior genetics. The Eysenck Personality Questionnaire (EPQ) measured three dimensions of personality: extraversion – introversion, neuroticism – emotional stability, and psychoticism – superego control, which Eysenck (1990) argued had biological foundations. He offered as evidence that analogous behavioral systems had been documented in nonhuman species, and twin studies documenting stronger personality correlations among separated monozygotic twins compared to dizygotic twins reared together (Eysenck 1990). Eysenck’s integrative approach speculated that personality traits emerged via physiological structures in the nervous system that in turn had emerged from genes. Over the years behavioral genomics, behavioral neuroscience, and other fields have further vindicate Eysenck’s speculations by linking individual differences to physiology and specific genes and have begun to elucidate the ways that environment operates on the genome. Eysenck’s influence on contemporary personality psychology is also evident in the overlap of his model with contemporary models of personality (Draycott and Kline 1995).

Today, the Five-Factor Theory of Personality or The Big Five represents one of the most fruitful approaches to conceptualizing and assessing personality (McCrae and Costa 1999; McCrae et al. 2000; McAdams and Pals 2006). The theory is named for five factors that are commonly derived when sufficiently broad measures of traits and behaviors are assessed: (1) neuroticism, (2) extroversion, (3) openness, (4) agreeableness, and

(5) conscientiousness. Each of the traits falls along a continuum and is normally distributed. Neuroticism refers to a continuum that ranges from emotional stability and calmness to high levels of negative emotionality, pessimism, and avoidant coping. Extroversion refers to the tendency toward positive emotions, sensation seeking, and gregariousness. Openness refers to the tendency to take on new experiences, enjoy novelty, and to consider the perspectives of other individuals. Agreeableness refers to the tendency to trust, empathize, and affiliate with others. Conscientiousness refers to tendencies to be orderly and rule following. Aspects of the Big Five are applicable across cultures and even so across multiple species. The former finding is of interest from an evolutionary perspective as it suggests that phylogenetic contingencies have shaped behavior throughout biological history to produce a human nature that is observable across diverse geographies and cultures. The latter finding is of interest as it may suggest common and/or convergent evolution. The Big Five traits are reliable over time and are useful for predicting behavior in occupational and clinical settings.

Personality, Development, and Change

Given the definition of personality as stable patterns of cognition, emotion, and behavior across situations, high heritability of traits, and high reliabilities of traits over the lifespan, there may be an erroneous perception that maladaptive personality traits are immutable. While it is true that behavior modification may require specific and intensive interventions to address maladaptive personality traits, fatalism, genetic essentialism and other assumptions may raise strong emotions, elicit stigma and create self-fulfilling prophecies that interfere with the prevention and/or modification of maladaptive personality traits and even health behaviors.

A number of studies demonstrating that personality can be altered by early life experiences, major life transitions, and focused psychological intervention challenge assumptions of genetic essentialism and reveal that personality may be more malleable than previously expected.

Exposure to early life adversity moderates the associations of alleles with depressive behavior (Caspi et al. 2003). Following the loss of a loved one to lung cancer, caregivers reported significant increases in prosocial traits (Hoerger et al. 2014). Dialectical Behavior Therapy is considered an evidence-based treatment for Borderline Personality Disorder, a pattern of behavior marked by emotional dysregulation, unstable sense of self, and interpersonal conflict (Kliem et al. 2010).

Contextual Mechanisms of Change

Sociogenomic personality psychology challenges the misconception that behavior is only determined by genes and evolution (Roberts and Jackson 2008). The sociogenomic perspective expands the Eysenckian model through its emphasis on genes working in accordance with the environment. Genes are regulated by the cellular environment and are also influenced by the outside environment. It is reasonable to believe that personality is environmentally dependent, which also means that genes must also be at play in this process. Thus, from the sociogenomic perspective personality traits may be more malleable than previously expected.

The move towards a sociogenomic study of personality psychology targets the study of the genome, rather than solely studying humanity (Roberts and Jackson 2008). This is because the genome is highly conserved across species and is responsible for not only behaviors in human beings, but also in all life forms. The study of the genome in all species will provide a greater understanding of the interaction between genes and the environment. This new perspective will allow us to map the pathway from gene to behavior, thus, enhancing knowledge of personality psychology (Roberts and Jackson 2008).

Conclusion

Personality refers to the characteristics that distinguish an individual. Traits are heritable and differ from one person to the next by genetic and environmental differences. Hans Eysenck, an

impactful personality psychologist, argues that personality psychology is rooted in biological systems. His approach speculates that personality traits stem from physiological structures that themselves surface from genes. A reliable and popular way to conceptualize personality is through the Five-Factor Theory of Personality (McCrae and Costa 1999; McCrae et al. 2000). The theory includes five factors that can justly measure traits and behaviors: (1) neuroticism, (2) extroversion, (3) openness, (4) agreeableness, and (5) conscientiousness. These traits are useful for predicting behavior in social settings. A newer approach to personality psychology is sociogenomic biology. This theory counters Eysenk by stating that genes are heavily influenced by one's outside environment. This approach breaks down the misconception that biological mechanisms are immutable and will ultimately provide a better understanding of personality psychology by mapping the pathway from gene to behavior.

Definition

A personality disorder is a pervasive and stable pattern of behavior that emerges in adolescence or early adulthood, in which distressing and impairing behaviors deviate from the expectations of the individual's society.

Introduction

The ten personality disorders (PDs) discussed in this chapter are divided into three clusters based on phenotypic similarity, according to the Diagnostic and Statistical Manual of Mental Disorders (5th ed.; DSM-5; American Psychiatric Association 2013). Cluster A PDs (paranoid, schizoid, and schizotypal) present with weak or nonexistent social attachments and odd/eccentric behavior, which may be an alternative expression of a schizophrenia predisposition (Miller et al. 2001). Cluster B PDs (antisocial, borderline, histrionic, and narcissistic) share common features with one another, such as impulsive acting out, unpredictable behaviors, and dramatic presentation (Sutker and Allain 2002). Finally, Cluster C PDs all have anxious, fearful, and inhibited traits in common (Miller et al. 2001).

Over time, the psychological field has held the perspective that PDs are not treatable; however, more recent research has shown benefits and a reduction of symptoms through various treatment approaches (Meloy and Yakeley 2014; Bateman and Tyrer 2004). Although there is mixed evidence for these findings, there is concrete support for treating borderline personality disorder (BPD) through dialectical behavioral therapy (DBT; Linehan 1993; Shearin and Linehan 1994). Aside from DBT, there are no other specialized treatment approaches for any of the remaining nine PDs. The author emphasizes the need for treatment of PDs as these are among the most frequent disorders diagnosed by psychiatrists (Zimmerman et al. 2005). Moreover, the majority of individuals with a PD have at least one other comorbid PD, along with additional disabling diagnoses (e.g., anxiety disorders, mood disorders, substance use disorders),

highlighting a greater need for treatment (Sutker and Allain 2002; Miller et al. 2001; Lieb et al. 2004; Bornstein 1995).

A huge problem in the psychological field is the lack of focus on Cluster A and C PDs, as Cluster B PDs (mainly antisocial and borderline) have dominated the academic literature. The majority of the Cluster A and C PDs discussed in this chapter have received few, if any, clinical trials, have limited information on their causes and etiology, and have no empirically supported treatment approaches. In this chapter, the author will discuss potential treatment methods, although there is limited empirical evidence supporting these approaches compared to the amplitude of literature supporting DBT. The goal of this chapter is to emphasize the lack of research on Cluster A and C PDs and raise awareness on the need for clinical trials and standardized treatment methods. Future researchers are encouraged to focus on Cluster A and C PDs to expand academic research and increase their knowledge concerning empirically supported treatment methods, while also striving to determine the evolutionary purpose of PD traits.

In order to understand the ten PDs, the author will outline the following key points for Cluster A, B, and C PDs: diagnostic criteria (see Tables 1, 2, 3, 4, 5, 6, 7, 8, 9, and 10), prevalence rates, sex differences, comorbid conditions, causes and/or risk factors, and treatment approaches. Readers are encouraged to contemplate the evolutionary benefits of these “negative” behaviors, as they have continued through natural selection for a reason – one that may harm society as a whole, but may benefit the affected individual (Hashmani and Jonason 2017). It is important to note that all PDs yield some sort of adaptive benefit, although society often views these behaviors as harmful.

The Ten Personality Disorders

Cluster A

Paranoid personality disorder. Paranoid personality disorder (PPD) is a pattern of distrust and suspiciousness, where others' motives are

Personality Disorders, Table 1 DSM-5 Diagnostic criteria for paranoid personality disorder

A. A pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

1. Suspects, without sufficient basis, that others are exploiting, harming, or deceiving him or her
2. Is preoccupied with unjustified doubts about the loyalty or trustworthiness of friends or associates
3. Is reluctant to confide in others because of unwarranted fear that the information will be used maliciously against him or her
